KEYWORDS: Basic Nitrogen, Middle distillates, NMR, HSQC, NMR Prediction, isoquinoline

ABSTRACT: Basic nitrogen-compounds (N-compounds), present in middle distillates, can inhibit acidic catalysts used in hydrotreatment processes. A better knowledge of these compounds, especially the environment of the nitrogen atom, may be interesting to improve these processes. Herein, we propose a new promising methodology coupling the extraction of the basic N-compounds by flash chromatography with 2D NMR analysis. The NMR sequence Heteronuclear Single-Quantum Correlation (HSQC) allows to visualize specific C-H correlations and, with the help of the prediction software Advanced Chemistry Development/Laboratory (PS-ACDL), eleven areas of interest have been identified. The representativeness of these areas have been validated with data from literature and with a gas oil (GO) sample analysis. These areas are specific to C-H couples in pyridine, quinoline, isoquinoline and acridine derivatives and give a detailed fingerprint of basic N-compounds in the GO cut. Moreover, certain areas allow to describe the close environment of the nitrogen atom and allow, for example, to differentiate isoquinoline from quinoline derivatives.

INTRODUCTION

Organic nitrogen compounds (N-compounds) in middle distillates are known for inhibiting the process of the hydrodesulfurization (HDS)¹⁻⁴. In the literature, these compounds are classically divided into two distinct groups: “neutral compounds” (derivatives of pyrrole) and “basic compounds” (derivatives of pyridine). This work is focused on basic N-compounds which are suspected to be potential inhibitors of acid catalysts. The basic N-compounds include pyridine, quinoline, acridine, benzoquinoline and their alkylated analogs^{5,6}. Besides pyridine, quinoline or acridine are often used as model molecules to investigate the influence of the N-compounds on the catalytic activity for HDS^{7,8}.

Nowadays, two-dimensional gas chromatography (GC×GC) is the most developed technique^{4,9} to characterize N-compounds in complex matrices, such as fossil fuels, especially when it is coupled with specific detectors like nitrogen chemiluminescence detector (NCD)^{3,10,14,15}, nitrogen-phosphorus detector, atomic emission detector¹¹ or mass spectrometry (MS)^{12,13}.

Although the high peak capacity of GC×GC, coelutions remain present, mainly between quinolines and anilines, indoles and quinolines or carbazoles and acridines. In order to narrow these coelutions, N-compounds are generally extracted from hydrocarbons by solid phase extraction (SPE) to give 2 isolated fractions: basic and neutral fractions^{16,17}. By coupling SPE and GC×GC, it is possible to access the accurate quantification of N-compounds by families like pyridines, quinolines or acridines. However, GC×GC does not allow to access information on the environment of the nitrogen atom. For example, 2,6-dimethylquinoline and 3,5-dimethylquinoline are quantified as quinolines by GC×GC-NCD even if the steric influence of the methyl group on positions 2 and 6 may change the reactivity of the nitrogen atom on an

acidic site of a catalyst. Similarly, GCxGC is not able to make the difference between an isoquinoline and a quinoline which have very similar structures but different basicities. Consequently, knowing the environment of the nitrogen atom could be just as important as quantifying the different families to describe the inhibitor character of a middle distillate.

In our previous work, we proposed an approach coupling SPE, derivatization with BF_3 of non protogenic nitrogen species and the use of NMR analysis¹⁸. By crossing information from ^{19}F , ^1H , ^1H - ^{19}F HMBC and ^{19}F DOSY, it is possible to determine the close environment of the nitrogen atom of the most nucleophilic nitrogen compounds in GO. However, the intermediate step of derivatization with BF_3 makes complex the procedure and its extension from a qualitative to a quantitative method.

During the previous work, we noticed that pyridine derivatives, extracted from a GO, showed specific chemical shifts in ^1H or in ^{13}C compared to their hydrocarbon analogues. In 1D NMR, these specificities are not enough to give accurate information about the structures of N-compounds. However, 2D NMR, coupling ^1H and ^{13}C , should increase the singularities of each C-H couples, facilitate their differentiation and their identification. Thus, the aim of this work is to demonstrate the possibility to access new information about the structure of the basic N-compounds and the environment of the nitrogen atom without derivatization prior to analysis by 2D NMR.

In the first part of this study, 2D NMR spectra of almost 150 basic aromatic N-compounds were simulated with Advanced Chemistry Development/Laboratory software¹⁹ (PS-ACDL). The resulting 2D NMR cartography of proton/carbon correlations shows isolated and specific areas which validate the main theory. In the latter part, different sequences were tested and adjusted to

the specificities of a real sample extracted from a coker GO. The theoretical and experimental cartographies were compared in order to validate the full approach.

EXPERIMENTAL SECTION

Chemicals. All nitrogen compounds were purchased from Sigma-aldrich and were used without further purification. Dichloromethane-*d*₂ (CD₂Cl₂) and chloroform-*d* (CDCl₃) were purchased from Euriso-top and dried on activated molecular sieves (3Å). The silica used for the extraction was Merck silica (40–63 μm, 0.8 cm³/g pore volume, 480–540 m²/g). Silica is kept at 110 °C for at least 24 h before use. The gas oil (GO) was obtained from a coker unit and it contains about 1200 wppm of nitrogen and 550 wppm of basic N-compounds. The coker GO was not hydrotreated.

Extraction Protocol on GO. Basic N-compounds were extracted by flash chromatography which was adapted from Chahen *et al.*¹⁸. PLC 2250 (Gilson) with silica column (40 g, Ø 30 mm) equipped with a UV detector was used for flash chromatography separation. The flow rate was kept at 40 mL/min for different solvents. Before use, the cartridge was conditioned with 200 mL of heptane, then 28,1 mL of sample was injected into the silica column. The hydrocarbon matrix was eluted from the column with 480 mL of n-heptane whereas N-compounds were trapped on the silica column. Neutral N-compounds and anilines were eluted off the column with 400 mL of dichloromethane while basic N-compounds were eluted with 240 mL of acetone. The acetone fraction was dried on MgSO₄ and filtered, and acetone was evaporated slowly in a rotary evaporator to give 200 mg of oily mixture.

NMR Experiments. Samples for NMR were prepared using 200 mg of basic N-compounds from the GO dissolved in 300 μL of the CD₂Cl₂ or CDCl₃. ¹H NMR (300.13MHz) and ¹³C NMR

(75.47 MHz) spectra were recorded on a Bruker Avance III NMR spectrometer with a BroadBand probe (BBFO) using 5 mm o.d. glass NMR tubes. The chemical shifts are reported in δ (ppm) values. ^1H NMR chemical shifts were referenced to the residual solvent peak: 5.32 or 7.26 ppm for proton resonance of dichloromethane or chloroform, respectively. ^{13}C NMR chemical shifts were referenced to the residual solvent peak: 53.84 or 77.16 ppm for carbon resonance of dichloromethane or chloroform, respectively. The pulse program "hjresqf" was used to measure coupling constants and different pulse programs "hsqc" from Bruker's library were tested to record Heteronuclear Single-Quantum Correlation (HSQC).

The 2D proton J-resolved spectroscopy experiments were acquired with for 64×512 points spectral widths of $400 \text{ Hz} \times 4500 \text{ Hz}$ ($F1 \times F2$), a $9 \mu\text{s}$ $\pi/2$ RF pulse length, a 2s pulse repetition time, 16 scans, and a total acquisition time of 38 min. The number of scans was adjusted according to the samples. For ^1H - ^{13}C 2D HSQC, spectral widths were approximately 1.2 kHz for ^1H dimension between 6 and 10 ppm and 6 kHz for ^{13}C between 95 and 175 ppm. Sensitivity-enhanced ^1H - ^{13}C 2D HSQC experiments were performed employing an INEPT transfer delay of 1.47 ms corresponding to a $^1J_{\text{C-H}}$ of 170 Hz. 256 free induction decays were collected along the indirect (t_1) dimensions using 32 scans per increment and a 4 s recycle delay, resulting in a total acquisition time of about 10 h for the ^1H - ^{13}C HSQC. Phase sensitive data were obtained using echo-antiecho mode with carbon (for ^1H - ^{13}C HSQC) decoupling during acquisition (t_2 dimension) using the GARP sequence.

Software and data base. The prediction software of the Advanced Chemistry Development/Laboratory¹⁹ (PS-ACDL) is mainly based on experimental data. When a molecule is in its database, the software gives the experimental spectra. When a molecule is not in its database, the software uses algorithms and experimental spectra from the closest molecules from

its database to predict a spectrum. PS-ACDL can predict ^1H and ^{13}C spectra in divers solvents since its algorithms consider also solvent effects. However, the version of PS-ACDL used in this work do not predict 2D NMR spectra. The correlations between ^1H and ^{13}C were done manually for each compound.

Spectral Database for Organic Compounds²⁰ (B-SDBS) is, inter alia, a database of NMR's spectra. This base was built from experimental spectra recorded usually in CDCl_3 and was used to compare with PS-ACDL.

RESULTS AND DISCUSSION

Model molecules

In the literature, basic aromatic N-compounds in acetone extract are separated in three families: pyridine, quinoline and acridine derivatives. Although suspected, isoquinolines are never considered since it is almost impossible to separate them from quinolines by $\text{GC}\times\text{GC}$ and to be clearly identified by mass spectrometry. 150 model molecules were considered with 15 pyridine, 47 quinoline, 45 isoquinoline and 43 acridine derivatives. The derivatives differ mainly from the head of the family by alkyl substitutions at different positions. According to literature, both the δ_{H} and the δ_{C} are weakly impacted by the nature of alkyl substituent (methyl, ethyl, isopropyl, etc...) ²¹⁻²³. Consequently, only methyl alkylations at different positions were considered. The full list of basic aromatic N-compounds simulated is reported in supplementary information (Table S1).

For each model molecule, both ^1H chemical shift (δ_{H}) and ^{13}C chemical shift (δ_{C}) of the aromatic cycle containing the nitrogen atom were determined by PS-ACDL. Each C-H correlation of a head of family is represented by a geometric form with a dark blue outline to

help visualization. PS-ACDL correlations were predicted in CDCl_3 since the database is the most complete.

The nomenclature of the different families is called to mind in the Table 1. This nomenclature respects the IUPAC nomenclature for pyridine, quinoline, isoquinoline and acridine derivatives. However, it was adapted for "Benzo derivatives" in order to keep the same position in relative to the nitrogen atom.

Comparison between PS-ACDL and B-SDBS

Pyridine derivatives are the simplest molecules of basic aromatic N-compounds with one single aromatic ring. B-SDBS contains the NMR spectra of 11 pyridine derivatives on the 15 simulated by PS-ACDL . So pyridine derivatives are ideal to compare the prediction of PS-ACDL with B-SDBS (Figure 1). The signals of pyridine (head of family) are easily located with a dark blue outline.

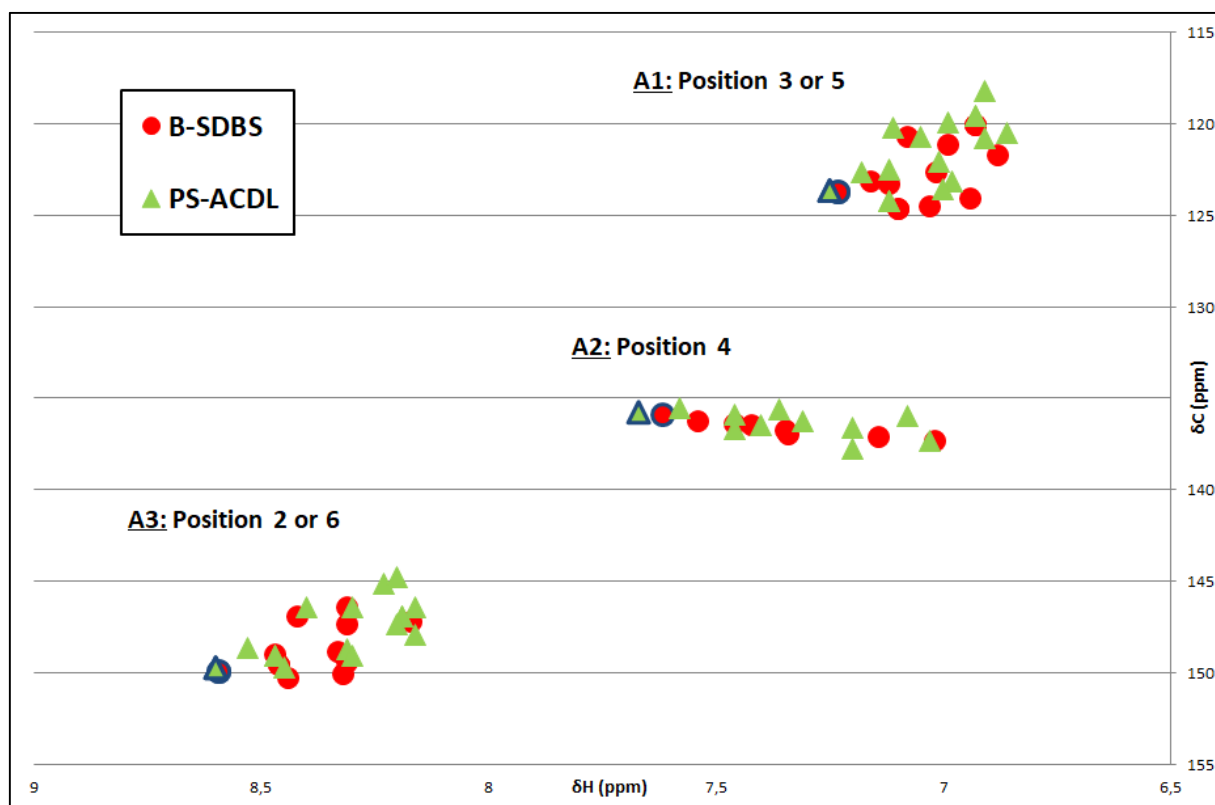

Figure 1. $\{^1H, ^{13}C\}$ HSQC spectra of pyridine derivatives simulated by PS-ACDL and given by B-SDBS.

With both prediction software and database, three distinct areas stand out according to the position of the C-H correlation relative to the nitrogen atom. In this study, the correlation of carbon in position n with proton in position n is noted C^n-H^n . To facilitate understanding, each area is numbered with a letter A following by a number. C^3-H^3 and C^5-H^5 correlations of

pyridine derivatives are gathered in A1, while C⁴-H⁴ correlations are regrouped in A2. A3 contains C²-H² and C⁶-H⁶ correlations.

The dispersion of predicted correlations with PS-ACDL is very close to those given by B-SDBS. In all cases, protons of pyridine in each area are always the most deshielded in ¹H NMR. This observation is confirmed by the literature with pyridine and alkylated pyridine derivatives²⁴. Finally, the predicted correlations made with PS-ACDL seem accurate and PS-ACDL can be used to predict quinoline, isoquinoline and acridine derivatives with confidence.

Prediction of C-H correlations

47 quinoline derivatives were considered. 34 have a proton in position 2, 35 have a proton in position 3 and 34 have a proton in position 4. The full cartography of this family predicted with PS-ACDL is given in Figure S1 in supplementary materials. This cartography is complex because of the presence of aromatic signals due to hydrocarbon aromatic cycle in quinoline structure. To facilitate the comprehension, these signals are removed in Figure 2 which allows to notice three new distinct areas: A4, A5 and A6.

C³-H³ correlations of quinoline derivatives are observed at δ_H/δ_C of 7-7.5/119-124 ppm and are gathered in A4. 32 out of the 35 quinoline derivatives simulated have their protons in position 3 located in this area. Only benzo(f)quinoline (represented by grey cross) with a correlation at δ_H/δ_C of 7.45/116.7 ppm and bisquinoline family have their C³-H³ signals outside this area. However, Jiang *et al.*²⁵ synthesized and analyzed benzo(f)quinoline. They indicated the C³-H³ correlation at δ_H/δ_C of 7.56/121.3 ppm which confirms that PS-ACDL has difficulty to predict C³-H³ correlations of benzo(f)quinoline. As a result, all C³-H³ correlations of quinoline and benzoquinoline derivatives are in the same zone A4. Few signals are more deshielded than

quinoline in ^1H NMR, but these belong to benzoquinolines or 8-hydroxyquinoline, two very specific species.

The area, corresponding to $\text{C}^4\text{-H}^4$ correlations of quinoline derivatives, is divided into two distinct parts: A5 and A5'.

- A5 extends from 7.8 to 8.3 ppm in ^1H and from 130 to 140 ppm in ^{13}C . A5 is located just below hydrocarbon aromatic protons signals. It groups 29 simulated quinoline derivatives.
- A5' has similar chemical shifts in ^{13}C but is most deshielded in ^1H (8.5-9.2 ppm). This area groups all $\text{C}^4\text{-H}^4$ correlations predicted for specific benzo(f)quinoline derivatives.

A5'' (zone colored in yellow in Figure 2) is a part of A5. This area corresponds to $\text{C}^4\text{-H}^4$ correlations of quinoline derivatives alkylated in position 5. The lower chemical shifts δ_{C}^4 of A5'' are validated in the literature where δ_{C}^4 for 5,8-dimethylquinoline²⁶, 5,7-dimethylquinoline²⁷ and 5-methylquinoline²⁸ are measured at 131.9, 132.4 and 132.7 ppm, respectively. In A5'', few signals are more deshielded in ^1H than quinoline. The literature confirms also these data, by reporting for 5-methylquinoline²⁸ and 5,7-dimethylquinoline²⁷, chemical shifts δ_{H}^4 of 8.31 and 8.26 ppm, respectively.

$\text{C}^2\text{-H}^2$ correlations of quinoline derivatives were observed at $\delta_{\text{H}}/\delta_{\text{C}}$ of 8.6-9.0/147-152 ppm and are gathered in A6. According to PS-ACDL, 32 of the 34 predicted $\text{C}^2\text{-H}^2$ correlations are in this zone. The two molecules outside A6 correspond to phenanthridine and 3,4-dimethylquinoline.

The $\text{C}^2\text{-H}^2$ correlation of phenanthridine was observed at $\delta_{\text{H}}/\delta_{\text{C}}$ of 9.31/153.76 ppm. B-SDBS confirms this correlation at $\delta_{\text{H}}/\delta_{\text{C}}$ of 9.26/153.5 ppm. This specific $\text{C}^2\text{-H}^2$ correlation is certainly due to the fact that phenanthridine can also be considered as an isoquinoline derivative.

Therefore, this correlation may be considered as a C¹-H¹ correlation of isoquinoline rather than a C²-H² correlation of quinoline.

The C²-H² correlation of 3,4-dimethylquinoline was observed at $\delta_{\text{H}}/\delta_{\text{C}}$ of 8.42/152.2 ppm. However, Yan *et al.*²⁹ synthesized this molecule and measured the C²-H² correlation at $\delta_{\text{H}}/\delta_{\text{C}}$ of 8.68/152.48 ppm which is finally located in A6.

PS-ACDL predicts a δ_{H} of 9.04 ppm for 5-methylquinoline which is higher than the δ_{H} of quinoline (8.91 ppm). Rousseaux *et al.*²⁸ synthesized this molecule and measured a δ_{H} of 8.90 ppm. This result confirms that PS-ACDL slightly tends to overestimate δ_{H} for quinoline derivatives and that quinoline can be considered as head of family.

According to PS-ACDL, even if benzenic correlations are closed to A4 and A5, they do not interfere with these areas. There is only one exception, at $\delta_{\text{H}}/\delta_{\text{C}}$ of 8.08/131.84 ppm (clear grey square in Figure S1). This exception corresponds to the correlation of 4,4'-dimethyl-2,2'-biquinoline. For this molecule, B-SDBS reports a correlation at $\delta_{\text{H}}/\delta_{\text{C}}$ of 8.23/130.56 ppm which was confirmed by Larionov *et al.*³⁰. So the correlation of this molecule was located outside A5".

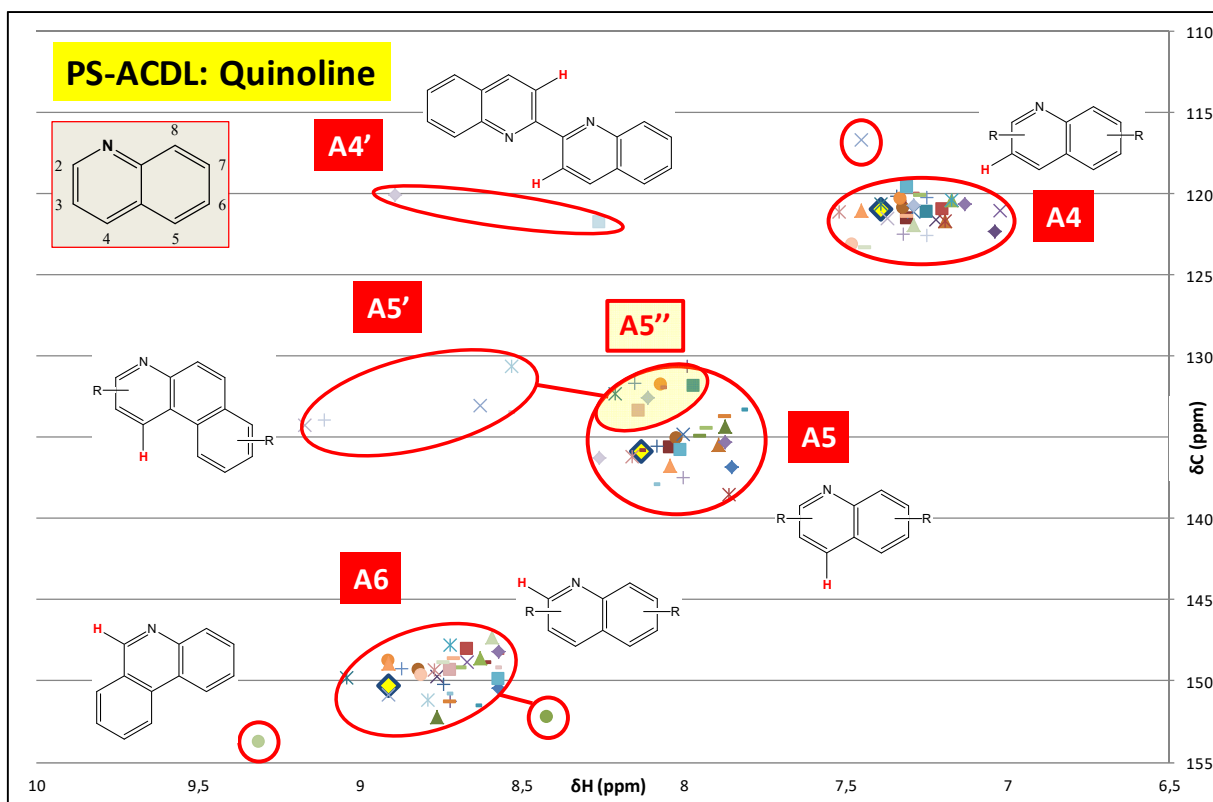

Figure 2. $\{^1\text{H}, ^{13}\text{C}\}$ HSQC spectrum of quinoline derivatives simulated by PS-ACDL without benzenic correlations.

Following the same approach as with quinoline derivatives, it is possible to establish different areas specific to pyridine, isoquinoline and acridine derivatives (Figure S2 to Figure S6 in supporting materials).

After correcting aberrant correlations by comparing with the literature and after controlling that each area did not interfere with benzenic correlations, all areas were gathered in the same graphic (Figure 3). Blue areas from A1 to A3 correspond to the three different C-H correlations of pyridine derivatives. Red areas from A4 to A6 correspond to the three different C-H correlations of quinoline derivatives. Green areas from A7 to A9 refer to the three different C-H

correlations of isoquinoline derivatives and, finally, purple area A10 contains C⁹-H⁹ correlations of acridines derivatives.

C¹-H¹ correlations of isoquinoline derivatives are located in three areas. The major part, 22 of 34 predicted correlations, is in A9. A9' contains isoquinoline derivatives substituted in position 8 which includes also benzo(h)isoquinolines derivatives. However, the very specific benzo(h)isoquinoline derivatives substituted in position 3 are located in A9".

C⁹-H⁹ correlations of acridine derivatives are divided in two parts. A10' regroups correlations of acridine derivatives substituted in position 1 or/and 8 while A10 clusters all other C⁹-H⁹ correlations of acridine derivatives. Unfortunately, A10' and A5'' are fully superposed and, consequently, it is not possible to separate the signals of C⁴-H⁴ correlations predicted for benzo(f)quinoline derivatives and the signals of C⁹-H⁹ correlations of acridine derivatives substituted in position 1 or/and 8.

There is also an important overlay between A1 and A4 which gather C³-H³ correlations of pyridine and quinoline derivatives. Other overlays can be considered as minor and have to be checked in details since the areas are delimited with regular ellipses and could be delimited more finely with non geometric forms.

Even if it is not possible to discriminate every correlation, it is interesting to distinguish at least correlations close to nitrogen atom (position *ortho*) of pyridine (C²-H² in A3), quinoline (C²-H² in A6) and isoquinoline (C¹-H¹ in A9, C³-H³ in A8) derivatives. A signal in these areas means that the corresponding nitrogen compound has at least an hydrogen atom in *ortho* position. Consequently, this *ortho* position is not sterically hindered and the nucleophilicity of the nitrogen atom is certainly higher than in hindered compounds. This compounds may certainly react faster and stronger with the acidic sites of a catalyst. Thus, the cartography may be a new tool or a new

way to understand, to describe and to predict the inhibitor character of middle distillates in hydrotreatment for example.

Figure 3. Prediction by PS-ACDL of C-H correlation in 2D NMR of pyridine (blue), quinoline (red), isoquinoline (green) and acridine (purple) derivatives.

The predicted cartography was realized in $CDCl_3$ because, in the literature as in PS-ACDL database, most of spectra of pyridine, quinoline or acridine derivatives were acquired in this solvent. Consequently, the software gives more reliable predictions in $CDCl_3$. However, using $CDCl_3$ as solvent presents disadvantages : i) $CDCl_3$ contents residual acids which can react with the basic nitrogen compounds to form pyridinium derivatives and generate chemical shifts. ii) The differences observed between the chemical shifts of a nitrogen compound alone and in mixture in $CDCl_3$ are generally significant in comparison to whose observed for CD_2Cl_2 as

example. iii) The residual solvent peak of the CDCl_3 in ^1H NMR is in the range of interest and may cause consequent artifacts by folding effect in 2D NMR with restricted spectral widths. Consequently, experimental 2D NMR spectra were done in CD_2Cl_2 keeping in mind that areas may be slightly shifted compare to predictions in CDCl_3 , especially in ^1H dimension since proton shifts are generally more sensitive to solvent change that carbon shifts.

2D NMR Spectroscopy of GO

Heteronuclear Single Quantum Coherence Spectroscopy (HSQC) and Heteronuclear Multiple-Quantum Correlation (HMQC) are used to correlate the chemical shift of ^1H (displayed on the F2 axis) to the ^{13}C chemical shift (on the “indirect,” F1 axis) of their directly attached carbon. HMQC spectra may have better signal to the noise ratio (S/N) than HSQC spectra because HMQC pulse sequence is significantly shorter³¹. However, HSQC spectra feature generally better line shapes than HMQC and the commonly used multiplicity-edited HSQC versions offer the added benefit of distinguishing CH_3 , CH_2 , and CH groups. Moreover, it is possible to use adiabatic ^{13}C -pulses in the HSQC sequence which can significantly improve the sensitivity of the signal and allows to make quantitative 2D NMR spectra^{32,33}. So, the HSQC is very often used for direct C-H correlations.

In HSQC pulse sequences, the total delay in the spin echo is important and depends on the magnitude of the one-bond carbon-proton coupling constant ($^1J_{\text{CH}}$). This delay time is routinely set according to an average $^1J_{\text{CH}}$ value of 145 Hz. However, in order to optimize the sequence, $^1J_{\text{CH}}$ of few model basic nitrogen compounds were measured and summarized in Table 2. Their coupling constants vary between 160 to 180 Hz. Consequently, a delay time of 170 Hz was chosen as average value. Several sequences were tested from the Bruker’s library. The sequence "hsqcetgpsi"³⁴ offers the best outcome. In this sequence, the lock is restored before the

acquisition. In certain cases, restoring the lock after the acquisition tends to improve the quality of the signal. Consequently, all experiments were recorded this way.

Table 2: Coupling constants $^1J_{CH}$ of different family in Hz

Position	Pyridine	Quinoline	Isoquinoline	Acridine
1	-	-	180,3	160,6
2	181,1	177,8	-	159,8
3	160,7	164,3	178,1	161,7
4	162,7	158,6	163,2	158,7
9	-	-	-	159,1

To decrease the time of acquisition, the signal was recorded only from 6 to 10 ppm in 1H and from 95 to 175 ppm in ^{13}C . This carbon spectral width was adjusted to avoid folding effects of alkyl signals on the areas of interest. GO was submitted to the extraction protocol described in Experimental Section and the basic nitrogen fraction was submitted to HSQC analysis. The HSQC spectrum of the GO is reported in Figure 4 with the areas of interest from Figure 3.

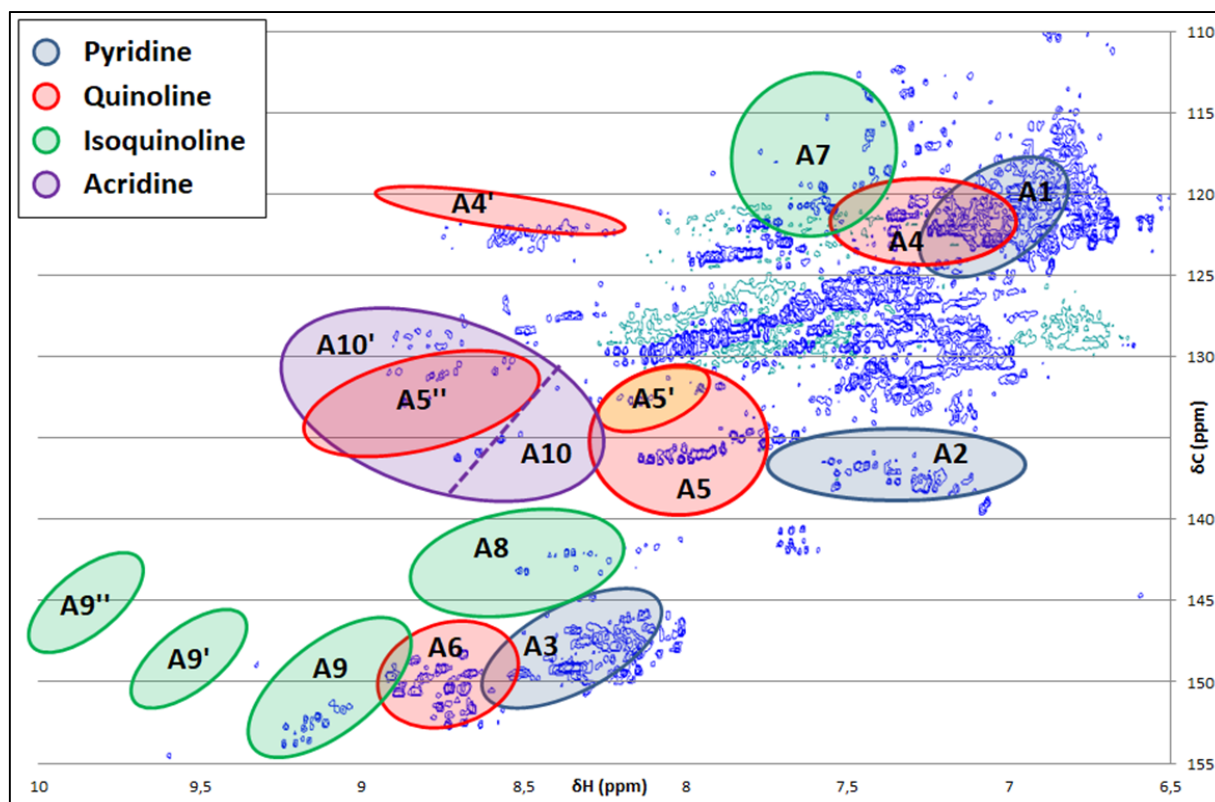

Figure 4. $\{^1\text{H}, ^{13}\text{C}\}$ HSQC spectra (300 K, 300 MHz, CD_2Cl_2) of the GO with areas as defined in Figure 3.

The signal observed under A1, A4 and A7 is diffuse and does not allow, as expected, to distinguish confidently these 3 areas. As expected too, the interference between A5'' and A10' makes impossible the assignation of the signals under these areas. Excepted these 5 areas, all others seem to be in accordance with the different groups of signals in the GO spectrum in HSQC. A2 and A3 of pyridine derivatives are faintly shifted from the corresponding signals. It would be necessary to adjust these areas, particularly A3 in order to not incorporate low intensity signals certainly belonging to isoquinoline derivatives and consequently to A8. A4' is slightly above the expected signal and seems less extensive than predicted. However, these compounds are so specific that a careful validation is required before validating this area. $\text{C}^4\text{-H}^4$ correlations

of quinoline derivatives are divided in two areas A5 and A5'. On the one hand, A5 is distinguishable and as expected, relatively well-separated from A2 and A10. On the other hand, the signals under A5' are less apparent which is certainly due to the fact that benzo(f)quinoline derivatives are specific molecules and present at low concentrations in this GO. For A6, the signal of this zone is framed by A3 and A9 but there is less overlap than predicted especially with A9. The signals corresponding to A9' seem more shielded and expanded than expected and no signal is visible on the spectrum under A9''. It may be necessary to accumulate more or to concentrate more the extract to observe these very specific correlations.

The signals corresponding theoretically to A8 are most shielded than predicted. Sarma *et al.*³⁵ made NMR spectra of isoquinoline and found at δ_{H} of 8.52 ppm in the CDCl_3 for the proton in position 3 instead of 8.8 ppm by PS-ACDL. This confirms the shift between the prediction and the signal obtained.

Overall, most of simulated areas match with groups of signals observed in the basic nitrogen fraction of the GO. However, certain areas seem slightly shifted from the corresponding signal. To confirm most of correlations, a few mg of pyridine, quinoline, isoquinoline and acridine were added to the GO extract. The spectrum obtained by HSQC is reported in the Figure 5.

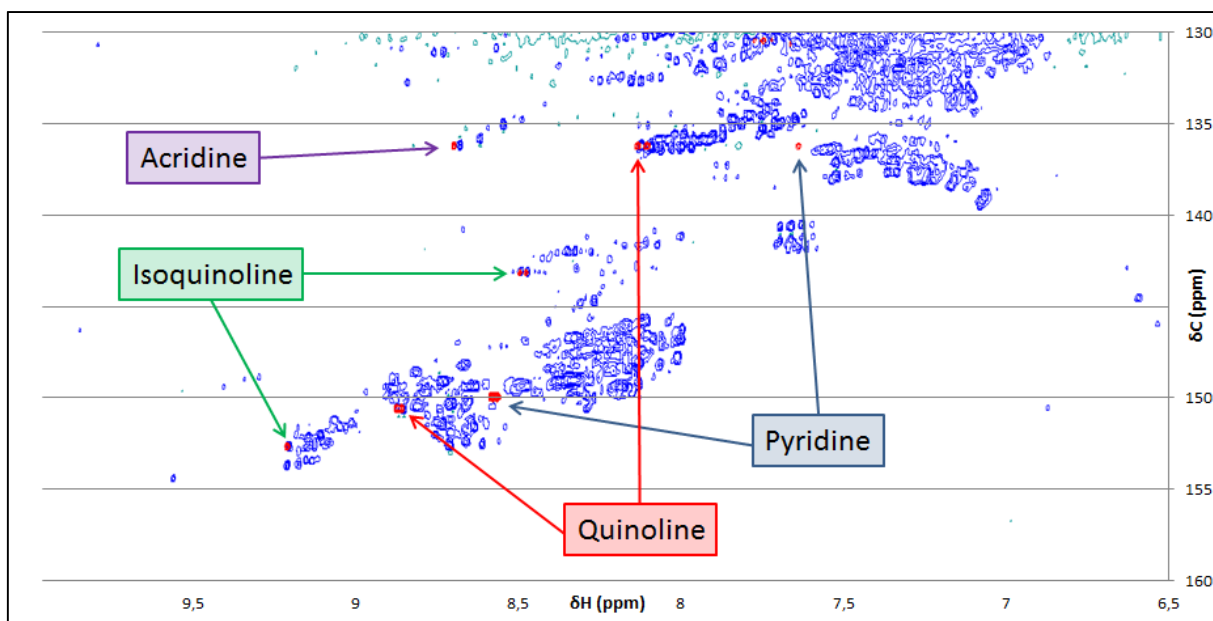

Figure 5. $\{^1\text{H}, ^{13}\text{C}\}$ HSQC spectra (300 K, 300 MHz, CD_2Cl_2) of the GO (blue spectrum) and the GO doped with pyridine, quinoline, isoquinoline and acridine (red spectrum).

As demonstrated previously, each head of family indicates the left limit of the areas and confirms the correlations. Especially, the position of isoquinoline signals corroborates with the data of Sarna *et al.* and confirms that A8 is located in a more shielded zone in ^1H NMR. Even if PS-ACDL predicts areas of interest with CDCl_3 as solvent, it is possible to distinguish and confirm most of these areas on HSQC spectrum of a GO in CD_2Cl_2 . These results confirm the interest of HSQC to enhance identification of basic N-compounds in GO. According to their localization, HSQC signals of basic nitrogen compounds give specific information about the alkylation on the N ring and also allow to differentiate isoquinoline and quinoline derivatives. Moreover, this can help identify new nitrogen species in middle distillates. For example, the well-distinct signals observed at $\delta_{\text{H}}/\delta_{\text{C}}$ of 7.65/141.3 ppm cannot be assigned to “classical basic nitrogen compounds” and the identification of this new family is still in progress.

CONCLUSION

A mapping of the correlations δ_H/δ_C at a specific position of the aromatic ring containing nitrogen was carried out with PS-ACDL on pyridine, quinoline, isoquinoline and acridine derivatives. After correction of few chemical shifts outliers with data from literature, it was possible to identify sixteen areas of interest. Even if PS-ACDL predicts areas of interest with $CDCl_3$ as solvent, it is possible to distinguish and confirm most of these areas on HSQC spectrum of a GO in CD_2Cl_2 by doping with pur compounds.

Consequently, a new methodology is available. It consists in extracting the basic compounds of middle distillate cuts by flash chromatography and analyzing the extracts by 1H - ^{13}C HSQC. The methodology allows to provide new fingerprint of structures of basic nitrogen species present in middle distillate cuts. This methodology was applied on a coker GO and achieves to demonstrate the presence of isoquinoline derivatives (not identifiable by GCXGC-NCD). Moreover, it gives very specific details on the close environment of nitrogen atom of basic N-compounds from GO. This methodology could be further expanded to heavier cuts like vacuum gas oils but work is in progress to firstly validate the quantitative aspect of the approach and maybe find new descriptors for inhibition or deactivation of hydrotreatment catalysts.
