#### 9 Abstract

10 Diagenetic models for silt-rich mudstone (siltstone) are less advanced than those for sandstone and clay-rich mudstone. In addition, the influences of diagenetic processes on 11 12 reservoir quality in siltstone formations are poorly understood. Here we examine the roles of depositional facies, detrital composition, and diagenetic processes in the compositional 13 14 evolution and reservoir quality of the Lower Triassic Montney Formation, a prominent siltstonedominated reservoir in western Canada with very large reserves of oil, gas-liquids and natural 15 16 gas. We applied advanced, high-resolution petrographic methods including SEM (SE, BSE, EDX 17 and SEM-CL), XRD, and QEMSCAN technologies, as well as He-pycnometry on samples from 18 17 different locations within the basin that represent a range of depths and thermal maturities. Cross-cutting and overgrowth relationships and volumes of authigenic phases demonstrate 19 20 massive precipitation of quartz, feldspar, dolomite, calcite and anhydrite cements at shallow burial 21 depths, leading to compositional homogeneity among different lithofacies. We propose that the precipitation of large volumes of cement resulted from high fluid flux through the formation at 22 23 shallow depth, possibly driven by reflux of concentrated seawater in nearshore saltpans. 24 Siltstones preserve relatively high porosity and permeability at shallow burial depths, differing from clay-rich mudstones. In contrast to sandstones, deep burial diagenesis played a relatively 25

26 minor role in the compositional evolution of the Montney Formation siltstone and is expressed in
27 the form of pressure solution and minor amounts of fibrous illite precipitation.

#### 28 **1. Introduction**

29 In contrast to clay-rich mudstones (shales), whose diagenetic evolution has received much attention (for example, Nadeau et al., 2005; Laughrey et al., 2011; Milliken and Olson, 2017; 30 31 Roberts and Elmore, 2018), coarser grained silt-rich mudstones (siltstones) are considerably understudied, with only one publication investigating the diagenesis of a pure siltstone (Orberger 32 and Pagel, 2000) that documents physical compaction, diagenetic alteration of detrital guartz, K-33 feldspar and mica and precipitation of calcite and dolomite cements. Although it has been 34 35 established that rock fabric (grain size and sorting) of mudstones significantly affects both 36 diagenetic processes and reservoir quality (Peng et al., 2020; Wilson et al., 2020), studies of the composition and diagenesis of mixed siltstone-mudstone or sandstone-siltstone sequences (e.g., 37 Varga et al., 2005; Taylor and Macquaker, 2014; Lai et al., 2016; Cao et al., 2017) rarely focused 38 39 on silty intervals, or grouped siltstones and fine sandstones together (McBride, 1989).

40 In this paper, we investigate diagenetic processes and their influence on reservoir quality of the siltstone comprising the Lower Triassic Montney Formation of the Western Canada 41 42 Sedimentary Basin (Armitage, 1962; Edwards et al., 1994; Zonneveld and Moslow, 2018). With 43 estimated reserves of 450 TCF of gas, 14,520 MMB of gas liquids, and 1125 MMB of oil (National Energy Board, Government of Canada, 2013), the Montney Formation is a major unconventional 44 45 host of hydrocarbons in the Western Canadian Sedimentary Basin (WCSB) and one of the most important siltstone hydrocarbon reservoirs in the world. The availability of long cores from a range 46 of burial depths and thermal maturities makes the Montney Formation an appropriate test case 47 48 for the investigation of siltstone diagenesis and its impact on reservoir properties. We examine the relationships between lithofacies, rock fabric (grain size and sorting), rock composition (detrital 49 50 and authigenic components and organic matter) and link these variables to reservoir quality.

51 Because porosity and permeability in the Montney Formation siltstone are functions of these 52 relationships, a thorough understanding of the temporal and geographic variability in these 53 components is key to understanding the paragenesis and development of this reservoir. The 54 sedimentary and diagenetic models developed in this study will facilitate the interpretation and 55 understanding of siltstone reservoirs elsewhere in the world.

#### 56 2. Geological setting

The Montney Formation covers over 130,000 km<sup>2</sup> in central and southwestern Alberta and 57 58 northeastern British Columbia (Fig. 1). The formation was deposited on the western margin of 59 Pangea during the Lower Triassic (Induan and Olenekian) (Davies et al., 1997; Utting et al., 2005; 60 Zonneveld et al., 2010; Henderson et al., 2018), in a back-arc to foreland setting (Ferri and 61 Zonneveld, 2008; Golding et al., 2016; Rohais et al., 2018). Paleogeographic reconstructions suggest that the basin was rotated approximately 30° clockwise from its current position and 62 positioned at 30° North (Golonka et al., 1994; Davies et al., 1997; Blakey, 2014). A hot, periodically 63 64 arid climate with seasonal monsoons prevailed in the region during the Lower Triassic (Davies, 1997; Golonka and Ford, 2000; Preto et al., 2010; Sun et al., 2012; Zonneveld and Moslow, 2018). 65 Extensive sedimentological studies of the Montney Formation describe deposition in a 66 67 westward-dipping and deepening basin. Depositional environments varied, and sediments 68 include shoreface facies, near-shore facies, off-shore successions, and submarine fans (e.g., Davies et al., 1997, 2018; Zonneveld et al., 2011; Playter, 2013; Crombez et al., 2016; Euzen et 69 70 al., 2018; Moslow et al., 2018; Zonneveld and Moslow, 2018). Sediments comprising the Montney 71 Formation were predominantly derived from the northwestern Laurentian continental margin to 72 the east of the basin, with a smaller contribution from the Inuitian orogenic wedge and the Yukon-73 Tanana accretionary terrain to the north of the basin (Fig. 1) (Ross et al., 1997; Beranek et al., 2010; Golding et al., 2016). The Meosin-Muinok high in the southwest part of the basin (Fig. 1) 74 75 was another potential sediment source, although it is not clear whether this high existed after the

Griesbachian (Early Induan) (Zonneveld and Moslow, 2014, 2018). Finally, a portion of the sediments in the Montney Formation may have been sourced from accretionary terrains postulated to have been positioned to the west of the basin in Early Triassic time (Zonneveld and Moslow, 2018 and reference therein) (Fig. 1).

The Montney Formation is subdivided into Upper, Middle and Lower Montney siltstone members. Other local members that are not discussed herein include the Pocketknife, Anten Coquina and Altares carbonate members, and the Calais and LaGlace Sandstone members. (Davies et al., 1997; Dixon, 2000; Moslow, 2000; Zonneveld and Moslow, 2018).

The Montney Formation unconformably overlies the Permian Belloy Formation (Fig. 2). The 84 Coplin and sub-Jurassic unconformities, formed during the Late Cretaceous Laramide Orogeny, 85 bound the formation from above in the eastern part of the basin (Gibson and Edwards, 1990; 86 Edwards et al., 1994; Davies et al., 1997; Moslow, 2000) and reduce its thickness to < 1m in 87 88 central Alberta. In the western section of the basin (northwestern Alberta and British-Columbia) where the Coplin unconformity cuts through younger intervals, the Montney Formation retains its 89 full depositional thickness, reaching over 350 m, and is overlain by the Sunset Prairie Formation 90 91 (Furlong et al., 2018) or the Doig Formation.

92 Burial history analysis indicates that from the time of deposition to the end of the Jurassic (a 93 time span of  $\sim$  100 million years), the formation was never buried deeper than 1000 m (Ness, 2001; Ducros et al., 2017). The Laramide Orogeny, beginning in the Early Cretaceous, triggered 94 95 rapid subsidence and initiated high sedimentation rates in the WCSB. The Montney Formation 96 reached its maximum burial depth and hence maximum temperatures at the culmination of this event (ca. 57.8 Ma) (Willett et al., 1997; Ness, 2001; Ducros et al., 2017; Rohais et al., 2018). 97 98 From the end of the Paleocene to present, the basin has undergone continuous erosion and uplift. 99 In its present configuration, the Montney Formation deepens from northeast to southwest from 100 less than 1 Km along the eastern subcrop to > 4 Km depth near the deformation front in the west. Corrected present day bottom-hole temperatures along this transect increase from <50°C to > 101

102 100 °C (BC Oil and Gas Commission, 2012), with only the southwestern edge of the formation 103 reaching temperatures >90°C. Thermal maturity ranges from  $R_0$ =0.59% in the northeast to  $R_0$ >2% 104 in the deeply buried southwest section (Riediger et al., 1990; Ibrahimbas and Riediger, 2004; Sanei et al., 2015; Crombez, 2016; Romero-Sarmiento et al., 2016; Wood and Sanei, 2016; 105 106 Crombez et al., 2017). Those trends are locally perturbed by syndepositional tectonism or paleotopography inherited from the pre-Triassic basin structure (Davies et al., 1997, 2018; 107 108 Moslow and Davies, 1997; Polt and Krause, 1997; Zonneveld and Moslow, 2014, 2018; Moslow 109 et al., 2018).

110 **3. Methodology** 

## 111 **3.1 Materials and sampling**

112 Our analyses are based on a combination of drill cuttings samples and conventional core samples, selected to represent a range of grain sizes and depositional environments. Table 1 113 summarizes sample types, sampling intervals, and analyses obtained from each study well. 114 115 Where possible, splits for all analyses were taken vertically from the same samples. Four long 116 cores were selected for extensive analyses, based on the availability of cores intersecting all or most of the Montney Formation interval. Two cores represent distal and deeply buried section of 117 the basin (wells 2 and 4 in Fig. 1); one well was selected to represent a more proximal, deeply 118 119 buried section of the basin (well 9), and the last well was selected to represent a proximal section 120 of the basin buried to a shallow depth. Additional thin sections (9) and core/outcrop samples (18) 121 from thirteen other locations were examined to provide comprehensive coverage of the formation.

#### 122 **3.2 Core description**

Detailed sedimentological descriptions were obtained for four cores (total length of 615 m, excluding a total of 51.5 m of missing core sections), recording sedimentary features as small as 1 cm to inform the suite of lithofacies present. Lithofacies were identified and distinguished on the basis of lithology, grain size, physical sedimentary structures, trace fossil assemblages, and bioturbation intensity (BI). The lithological classification scheme was adopted from Macquaker
and Adams (2003). According to this classification, a rock description is based on its sedimentary
structures and all components that form more than 10% of the rock volume; mudstones are
defined as rocks comprised of at least 50% grains that are silt-size or smaller. A rock can be
dominated by a component (>90%), rich in a component (50-90%) or bearing a component (1050%).

Lithofacies were divided into three groups based on their present-day apparent grain size distribution as measured by QEMSCAN analysis (see below). Present-day apparent grain size includes the detrital grain and cement overgrowths if present and thus reflects both the water energy in the environment of deposition and the amount of cement surrounding the detrital grains.

## 137 3.3 Petrography

Petrographic observations were obtained from thin sections SEM and SEM-CL analyses. 138 Grain size in most samples is coarse silt size or smaller (<63 µm), rendering a point count via 139 140 standard optical microscopy unreliable. Therefore, quantitative data was collected from Scanning 141 Electron microscopy (SEM) images, and thin section analysis focused on identifying coarse diagenetic phases (calcite, dolomite, and anhydrite cements). Thin section samples were selected 142 143 to represent all lithofacies described in the four cores. Thin sections were polished to 30 µm and 144 one-half of each thin section was stained with alizarin red and potassium ferricyanide to facilitate 145 carbonate mineral identification. We examined 73 thin sections under an Axio Zeiss Scope.A1 146 optical microscope equipped with a CITL Mk5 cold-cathode cathodoluminescence unit.

We used SEM analysis to study mineral morphology, distinguish between detrital grains and cements, constrain the paragenetic sequence based on overgrowths and cross-cutting relationships between minerals and define the timing of cementation relative to compaction. Petrographic analysis was also used to identify grain- or cement-supported fabrics and to distinguish mobilized hydrocarbons from depositional macerals.

Both freshly exposed surfaces of broken core chips and polished or ion-milled surfaces were examined by SEM. Polished samples were ion-milled with a Fischione Model 1060 SEM Mill at the University of Alberta. All samples were coated with gold or carbon prior to SEM investigation. SEM and energy dispersive X-ray spectroscopy (EDS) analysis was carried out on a JEOL 6301F Field Emission SEM (FE-SEM) or a Zeiss EVO LS15 EP-SEM, with an accelerating voltage of 20 kV, at the University of Alberta.

To evaluate cementation volumes and detrital quartz grain size, 17 ion-milled samples were 158 analyzed with a FEI Quanta 250 FEG SEM equipped with a GATAN MonoCL4 detector (SEM-159 CL) and a Bruker Quantax EDX at the University of Calgary. For each sample, three (1000X 160 magnification) or four (750X magnification) areas perpendicular to bedding were randomly 161 selected, and secondary-electron, back-scattered electron, and cathodoluminescence images 162 163 were recorded, along with energy-dispersive spectra. A 437-point grid was used for point counting 164 on each image. EDS elemental maps were used to identify the mineral at each node, and SEM-CL images were used for separating detrital from authigenic phases. Errors associated with point 165 count analysis were calculated following the method described in Van Der Plas and Tobi (1965). 166 167 Detrital grain size was determined by measuring the longest axis of all detrital quartz grains within 168 each image, and sphericity ratio was obtained by dividing the short axis by the length of the 169 perpendicular, long axis at mid height.

170 3.4 Mineral composition and grain size

Mineralogical compositions for a large number of samples were also obtained through QEMSCAN analysis. Quantitative x-ray diffraction (XRD) analysis was conducted on a sample subset to verify QEMSCAN analysis results. All 178 drill cutting samples (wells 3, 5, and 11), together with 238 core chips samples collected in constant intervals (wells 2, 4, 9, and 15) and 297 pseudocutting samples (well 7) were selected for mineralogical analysis. A ~5 g sub-sample was randomly separated from each drill cuttings sample and analyzed. From each core samples,

a small (~ 2 cm<sup>2</sup>), visually representative chip was cut perpendicular to bedding and analyzed.
For well 7, a continuous sliver was cut along the entire length of the core and divided into 1-m
intervals. Each interval was then crushed and mixed to generate pseudo-cuttings and a random
subsample from each section (~50 g) was analyzed.

181 Quantitative mineralogical compositions, including clay minerals, average mineral size for 182 each of the mineralogical phases identified, average grain size for feldspars and macroporosity 183 values (pores >5 µm), were determined by QEMSCAN analysis at SGS Canada laboratories in 184 Burnaby, BC, Canada. Repeatability of QEMSCAN measurements is very high (commonly <2%) 185 difference between repeated measurements of the same sample (M. Power, pers. com.). Compositional and porosity analysis by QEMSCAN is limited by the pixel size selected for 186 analysis, 4.8 µm in this study. However, clay minerals in our samples were commonly aggregated 187 188 rather than forming isolated laths, and we found that a pixel size of 4.8 µm was sufficient for 189 appropriate description of the rock.

Mineral size reported from QEMSCAN analysis is an average calculated from the horizontal intercept lengths of mineral crystals within a sample. However, if crystals of the same mineralogical phase are adjoining, QEMSCAN analysis might report those grains as a single large particle. For this reason, grain size results from QEMSCAN analysis that were larger than the 95<sup>th</sup> percentile (P<sub>95</sub>) were considered outliers. For a further discussion of estimates of particle size from QEMSCAN data, see Appendix 4.

To obtain grain size (as opposed to particle size) from QEMSCAN analysis, the mineral phase of interest was isolated from the dataset and touching particles were separated. Particles were then grouped into size-bins by the length of their apparent long axis. Results are reported as percent area of the mineral in each size-bin. We obtained grain size from both K-feldspar and Nafeldspar and calculated the weighted average grain size for each sample based on the relative abundances of the two feldspars. Grain size was not obtained for quartz grains because we were unable to separate touching grains sufficiently. To overcome this, we manually measured the

average quartz grain size on SEM images of 17 samples and then compared the results with the average grain sizes obtained from QEMSCAN analysis of feldspars. This comparison revealed that the average quartz grain size (measured manually) deviated ±5 µm from the average feldspar grain size obtained from QEMSCAN analysis. Since this deviation is close to the minimum detection limit of the QEMSCAN, the weighted average of feldspar grain size is sufficient for describing grain size distribution in our samples.

209 For grain size analysis, a bin width ( $\sim 1\phi$ ) was selected to avoid data skewing due to pixel size 210 (4.8  $\mu$ m). Bins are very fine silt (4.8-7.8  $\mu$ m), fine silt (7.8-15.6  $\mu$ m), medium silt (15.6-31  $\mu$ m), coarse silt (31-63 µm), very fine sand (63-125 µm), and fine sand (125-250 µm). Grains with clay 211 compositions are considered to be clay-size, confirmed by petrographic analysis (see section 212 4.3). Although an effort was made to separate touching grains, it is possible that not all such 213 214 contacts are identified, particularly where grains touched along a flat contact. Similar to the 215 mineral size analysis, inclusion of touching grains in the dataset may have slightly skewed results 216 towards coarser grain size. The error associated with measuring grain size using this method is 217 difficult to assess, but the error is largest where associated with measuring grains that are close 218 to the pixel size (i.e., grains with diameter close to 5 µm). Present-day grain size frequency 219 distribution properties were calculated with the geometric formulas proposed by Folk and Ward 220 (1957).

Twenty-six samples representing all lithofacies from all cores were selected for quantitative 221 bulk composition and clay mineral XRD examination. Six samples were analyzed at the James 222 223 Hutton Institute, Aberdeen, Scotland. X-ray diffraction patterns were recorded with a Panalytical Xpert Pro instrument using Ni-filtered CuKa radiation and an Xcelerator position-sensitive 224 detector, counting for 100 seconds per 0.0167° step between  $3-70°2\theta$ . The clay fraction (<2µm) 225 226 was separated by timed sedimentation in water, prepared as oriented mounts on glass and 227 scanned between 3-45°20 in the air-dried state and after glycolation. The remaining 20 samples were analyzed at the Mineralogy Facility at the Indiana University in Bloomington. X-ray diffraction 228

patterns were recorded with a Bruker D8 Advance X-Ray Powder Diffractometer, using CuKa
radiation and a Si(Li) energy-dispersive detector, counting for 2 seconds per 0.02° step between
2-70°20. A large sample (~250 g) was finely ground and the clay fraction (<2µm) was separated</li>
by timed sedimentation in water. Clay concentrates (< 1 g) were prepared as randomly oriented</li>
mounts on zero-background quartz plates and scanned between 2-20°20 in the air-dried state
and after glycolation.

# 235 3.5 Porosity

Residual (present day) porosity in the siltstone is a product of mechanical diagenesis
 (compaction), chemical diagenesis (cementation and dissolution), and organic matter diagenesis.
 Estimates of residual porosity assist in assessing the portion of original porosity lost due to
 diagenetic processes. QEMSCAN analysis provided the cumulative area of pores larger than 4.8
 µm. This macroporosity (pores >50 nm; Rouquerol et al., 1994) includes open pores and pores
 occluded with organic matter. QEMSCAN macroporosity values are reported for all drill cutting,
 pseudocutting and core samples analyzed.

243 Point count analysis provided values for primary porosity, secondary porosity, and porosity filled with organic matter for 17 samples. In addition, matrix porosity was measured at Trican (now 244 245 AGAT) laboratories in Calgary Alberta (136 samples from wells 2, 4 and 15), Core Laboratories 246 in Calgary, Alberta (109 samples, well 7), or Terratek, in Salt Lake City, Utah (50 samples, well 3), all using a Quantachrome Pentapyc analyzer 5200e. Samples from wells 2, 4, and 9 were 247 248 taken from gas-producing wells and did not require cleaning prior to testing. Samples from well 15 (an oil-producing well) were cleaned prior to testing in a Dean-Stark device using a mixture of 249 acetone (30 wt%), methanol (23 wt%), and chloroform (47 wt%). Matrix porosity comprises all 250 pores larger than the helium atom radius (1.4 Å) and is thus considered the sum of macroporosity 251 (pores >50 nm), mesoporosity (pores between 2 and 50 nm) and microporosity (pores <2 nm) 252 253 (Rouquerol et al., 1994).

#### 254 3.6 Organic Matter

Organic matter fills a portion of the pores in the siltstone. It is thus important to account for this phase when evaluating the porosity in the rock. Drill cutting samples (153) were analyzed for total organic content (TOC) using a RockEval VI pyrolysis at IFPEN, France. Details of this analysis are described in Crombez et al. (2016). In addition, 153 core samples and 109 pseudocutting samples were analyzed for TOC using the LECO-TOC method at Geomark Laboratories, Humble, Texas.

261 **4. Results** 

#### 262 4.1 Core Description

Fourteen lithofacies were identified in the four long cores (Table 2, Fig. 3). Lithology and physical sedimentary structures were the primary criteria used to characterize these facies, but in the upper parts of the formation, (sections that were reassigned to the Sunset Prairie Formation (Furlong et al., 2018), ichnological characteristics were also important. Core descriptions for the four wells are provided in Appendix 1.

All lithofacies described in this study but one (lithofacies D, a mudstone, comprising 0.2% of 268 269 the total core length examined) are either silt-dominated or silt-rich mudstones. In the distal 270 downdip wells 2 and 4, the most abundant lithofacies are the laminated siltstone (lithofacies G/H) 271 and the massive siliceous clayey siltstone (lithofacies J), both of which contain 86% silt-size arains. Other important lithofacies in the distal wells are the faintly laminated calcareous siltstone 272 273 (lithofacies F, 83% silt), and the interbedded siliceous-mudstone and calcareous- siltstone (lithofacies P, 87% silt). The bioturbated, calcareous, sandy siltstone (lithofacies M/N, 73% silt) is 274 found only at the uppermost section of the two distal cores and is part of the Sunset Prairie 275 Formation (Furlong et al., 2018). Lithofacies G/H (laminated siltstone), and lithofacies J (massive 276 277 siliceous clayey siltstone) were also identified in the section identified as the Sunset Prairie 278 Formation but are not exclusive to this unit, (Table 3).

In the deeply buried proximal (to the Meosin Muinok High; Fig. 1) well 9, the most abundant lithofacies is the massive sandy siltstone (lithofacies B). The average silt and sand contents in this lithofacies are 76% and 19%, respectively, but both grain size classes are quite variable (47-87% for silt; 6-47% for sand). Other important lithofacies in well 9 are the massive siliceous clayey siltstone (lithofacies J, 86% silt) and the hummocky to ripple cross-stratified sandy siltstone (lithofacies O, 82% silt).

In the proximal, shallow buried, updip well 15, the dominant lithofacies is interlaminated siltstone and sandstone (lithofacies A). This lithofacies displays a wide range of silt and sand content. Silt content varies between 31 and 87% with an average of 65%, and sand content varies between 9 and 40% (2 samples have higher sand content of 62 and 53%) and an average of 23%. Dolomitic siltstone (lithofacies E) is the second major lithofacies in well 15. This highly dolomitized lithofacies contains 78 to 98% silt grains (average of 84%), and up to 3% sand grains (average of 2%).

292 4.2 Grain size distribution

Mudstones are defined as rocks composed predominantly of clay- and silt-size grains (< 62.5  $\mu$ m) (Aplin et al., 1999; Flemming, 2000; Macquaker and Adams, 2003; Lazar et al., 2015). Fig. 4 shows the average and range of cumulative grain size distribution for each lithofacies. The graphic statistical variables (Folk and Ward, 1957) were calculated for each sample from the graphs in Fig. 4.

Samples were also grouped into larger grain-size bins: sand (>  $63 \mu$ m), silt ( $4.8 - 63 \mu$ m) and clay (< $4.8 \mu$ m) and plotted on a ternary diagram. Based on a combination of the Folk and Ward (1957) classification and the Macquaker and Adams (2003) classification, lithofacies were divided into three groups (Table 4, Fig. 5). Group one lithofacies (lithofacies A, B, C, E, M/N, and O) are somewhat coarser than other lithofacies and most samples in this group contain >10% sand size grains. Samples in these lithofacies are poorly to moderately sorted ( $0.5 < \sigma 1 < 1.5$ ) with a

positively skewed grain size distribution (tail of fine grains), and have sedimentary structures such
 as current ripples, hummocky cross stratification, and rip-up clasts indicative of higher water
 energy in the depositional environment (Table 2).

Group two lithofacies (lithofacies G/H and I) are siltstones with up to 10% sand content, 307 308 moderately sorted (0.5 <  $\sigma$ 1 < 1) and have a nearly symmetrical grain size distribution (skewedness ~ 0). Samples in this group are commonly laminated. Group three lithofacies 309 310 (lithofacies F, J, K, L, and P) are all fine grained, with <5% sand size grains, all moderately sorted  $(0.5 < \sigma 1 < 1)$  with a negatively skewed grain size distribution (tail of coarse grains). With the 311 312 exception of lithofacies P, samples in group three are massive in appearance. Lithofacies F (faintly laminated calcareous siltstone) showed a somewhat different grain size distribution in 313 samples taken from well 2 and well 5. Although the mode in samples taken from these two wells 314 315 is different from the other wells, (36.72 µm for well 2 and 69.74 µm for well 15), statistical variables 316 are not significantly different for samples from either of the two wells, or for the combined dataset of all samples (Table 2.3). Consideration of the error associated with the graphic statistical 317 parameters do not change classification of any of the lithofacies. 318

319 4.3 Detrital grain assemblage

320 Total mineral compositions obtained from QEMSCAN analysis, including diagenetic phases, 321 for samples from all wells are shown in Fig. 6. Quantitative XRD results confirm QEMSCAN findings (appendix 4). Detrital minerals were identified through SEM-CL analysis and guantified 322 323 by point count analysis on SEM-CL images (Table 4). Detrital quartz occurs as angular to subangular grains (Fig. 7a, i-l) and constitutes an average of 25.5% of bulk rock composition and 324 325 71.3% of total quartz (Table 4). Detrital chert grains (2.7% of bulk composition and 7.4% of total 326 quartz) are identified by mottled blue-red luminescence pattern, and a microporous texture of 327 silica particles that contain abundant porosity and inclusions (Fig. 7b, c). Rare collapsed 328 agglutinated foraminifera, identified by a prominent midline, are present (Fig. 7d).

Detrital feldspar grains are angular to subangular (Fig. 8). K-feldspar and Na-feldspar average 6.9% and 6.1% of bulk samples, 67.7% and 66.0% of total feldspar, respectively. Under the optical microscope, feldspar grains are commonly weathered along cleavage planes and variably dissolved.

All micas and most clays in the siltstone are of detrital origin. Micas include muscovite and 333 334 biotite. Mica grains are subangular to subrounded, and many are bent, displaced along cleavage 335 planes, and have splayed edges in response to compaction (Fig. 9a). Based on QEMSCAN 336 analysis, muscovite has the highest concentrations of all micas (up to 7.5 wt%), chlorite has a maximum concentration of 4.2 wt%, and biotite is present only in minor amounts (<1.5 wt%). 337 Chlorite was recognized in both QEMSCAN and XRD analyses and was identified in SEM 338 analysis as detrital material of metamorphic origin based on appearance and relatively coarse 339 340 grain size (Fig. 9a) (also noted by Zonneveld and Moslow, 2018; Moslow et al., 2018) and is 341 similar in morphology to other mica grains. Mica-like chlorite in our samples is susceptible to 342 dissolution and breakage along cleavage planes (Fig. 9b).

Mixed layer illite-smectite (MLIS) clays are present as clay coats (Fig. 9c) and aggregate 343 344 grains between detrital grains (Fig. 9d). MLIS is present in all the samples examined, but 345 concentrations determined by QEMSCAN analysis vary across the basin from just under 1 wt% to over 30 wt %. Point count analysis results (Table 4) are somewhat lower than the QEMSCAN-346 347 reported concentrations, with average total clay content of 3% and a maximum of 7%. XRD analysis of glycolated clay mounts established a maximum of 5% expandable layers for MLIS 348 349 throughout most of the basin. In only three samples (well 16 from the Dixonville Delta) does MLIS show higher expandability of 20%. 350

Dolomite occurs predominantly as rounded to well-rounded detrital grains, surrounded by rhombohedral overgrowths. These grains are identified by their bright luminescence, weathered (cloudy) appearance in thin sections (Fig. 10a), and the presence of dissolution pits (Fig. 10b) that are commonly <1.5 µm in diameter but locally larger in samples from cores 15 and core 9 (>5

μm) (Fig. 10d). Total dolomite concentration averages 17.5% of bulk composition. Only a third of
 the dolomite in the Montney is of detrital origin (Table 4; 5.4% of bulk composition and 32.2% of
 total dolomite on average); the remaining fraction is diagenetic in origin.

Detrital grains of different minerals vary in size. However, since detrital quartz is the least susceptible to dissolution in our samples, we used it as a proxy for detrital grain size, measured on SEM-CL images for samples from wells 2, 4, and 9. Detrital quartz grain size ranges in individual samples from 1.4 to 95.6  $\mu$ m, but most of the grains measured (P<sub>5</sub>-P<sub>95</sub>) show a narrower range of 3.5 to 42.15  $\mu$ m. Wells 2 and 4 have a smaller detrital quartz grains (average 12.65  $\mu$ m) than well 9, which averages at 25.2  $\mu$ m. The sphericity index (short grain axis / long grain axis) is 0.55 ± 0.20 for all three wells, indicating a majority of elongated detrital quartz grains.

#### 365 4.4 Authigenic phases

366 Authigenic minerals were identified through thin section, SEM and SEM-CL analyses. Cement 367 volumes were quantified from point count analysis of SEM-CL images (Table 4).

368 **4.4.1 Quartz** 

369 Two generations of authigenic quartz are present (Fig. 7a). The earliest, more abundant generation exhibits blue cathodoluminescence and comprises an average of 5.1% of mineral 370 371 volume, and 14.2% of total quartz. The second generation of quartz cement is identified by bright red cathodoluminescence and forms thin rims surrounding the blue guartz cement or detrital 372 quartz grains. Red luminescent quartz cement averages 2.3% of bulk composition and 7.0% of 373 374 total guartz. Fractured guartz grains are uncommon, with linear fractures typically 1 µm in width. 375 Fractures are filled with either blue or red quartz cement (Fig. 7 i, j). Rarely, a complicated network of red cement fills fractures developed in blue cement (Fig. 7k) or shattered detrital quartz grains 376 (Fig. 7l). 377

SEM images of freshly broken surfaces show that quartz cement forms overgrowths (Fig. 7e), euhedral microcrystalline cement (Fig. 7f), and silica nanospheres (Fig. 7g) (terminology adopted from Longman et al., 2019). Development of quartz overgrowths was inhibited to some degree by detrital clay coating (Fig. 7h), and in many cases overgrowth surfaces are speckled with angular holes <1 $\mu$ m (Fig. 7i). Silica nanospheres are a minor phase, locally forming grain coats that are too thin to identify in polished samples.

## 384 **4.4.2 Feldspars**

385 Authigenic feldspars have dark cathodoluminescence under SEM-CL (Fig. 8). K-feldspars and albite each form in a single overgrowth generation (Fig. 8a, b), and K-feldspar also forms discrete 386 387 euhedral crystals (Fig. 8c). Feldspar cement constitutes 32.3% and 21.4% of total K-feldspar and 388 total albite, respectively. K-feldspar cement overgrows detrital grains of both feldspar types (Fig. 8a, e), whereas albite cement overgrows only detrital Na-feldspar (Fig. 8b). A low-luminescing 389 albite appears to replace both K-feldspar (Fig. 8d) and Na-feldspar (Fig. 8e). We note that these 390 391 grains might also be interpreted as plutonic detrital grains with low luminescence albite. However, 392 we favor the interpretation of albitization due to the nonlinear morphology of the low-luminescing albite and its association with porosity that is potentially secondary (Milliken, 1989). Replacive 393 394 albite accounts on average for 13.5% of total Na-feldspar.

Extensive dissolution of K-feldspar cement is a minor phenomenon but is important locally. Dissolution occurs mainly along the boundary between the detrital grain and the cement rim (Fig. 81) and is most common in Well 15, and to a lesser degree in Well 9.

398 **4.4.3 Dolomite** 

At least four generations of dolomite cement were identified under CL and SEM-CL microscope (Fig. 10a, b). Absence of evidence for dissolution of authigenic dolomite, and sharp transitions between cement generations suggest continuous cementation with rapidly changing fluid composition. The last dolomite generation is an iron-rich dolomite (Fe ~ 5 wt%, based on 403 QEMSCAN analysis), easily identified by the brighter BSE signal and quenched 404 cathodoluminescence (Fig. 10b). In some samples, iron-rich dolomite replaces earlier dolomite 405 cements (Fig. 10c), and occasionally detrital dolomites.

Authigenic dolomite amounts to 12.1% of rock volume on average, and 67.8% of total dolomite, and in most samples, more than 30% of the total dolomite is Fe-rich. Dissolution pits in detrital dolomite are either empty or filled with authigenic pyrite, phosphate, and rarely quartz and K-feldspar (Fig. 10a, b).

410 **4.4.4 Calcite** 

411 Most calcite occurs as pore-filling poikilotopic cement (Fig. 10e) and to a much lesser extent 412 as a replacive phase after detrital dolomite (Fig. 10f). Calcite concentrations vary greatly and 413 unpredictably and range between 0.1 and 40.8% of the rock volume. Two generations of poikilotopic calcite were identified (Fig. 10g), indicated by different intensities of blue 414 cathodoluminescence. The first calcite cement generation (37.1% of total calcite) contains 415 416 euhedral pyrite inclusions. The second calcite cement generation (62.3% of total calcite) has the 417 same CL pattern as the calcite that replaces dolomite. Point count analysis establishes that calcite that replaces dolomite accounts for < 1% of total calcite in the Montney Formation (Table 4). 418 419 Moldic porosity and associated dolomitic and possible phosphatic infill cements of shells and other 420 bioclasts (Fig. 10h, i) are evidence of dissolution and/or replacement of the primary aragonite or 421 calcite.

#### 422 4.4.5 Clay minerals

Kaolinite is present in significant amounts ( $P_{50}>1.75$  %) only in wells 11 and 15. Samples from wells 15 and 16 also contain abundant authigenic kaolinite crystals and vermiform kaolinite that fills open pores (Fig. 9e). Authigenic fibrous illite is pore-bridging and pore-lining, nucleating on detrital clays (Fig. 9f), mica grains, and rarely on kaolinite. Fibrous illite abundance has no clear relationship to burial depth or lithofacies association. In addition, fibrous illite crystal growth is not

uniform, with fiber lengths varying from several micrometers in some samples to less than one
micrometer in others. We observed no clumping of illite fibers that can sometimes occur in airdried samples. In the quantitative data from the QEMSCAN analysis, fibrous illite is grouped
together with MLIS clays.

#### 432 **4.4.6** Pyrite, anhydrite, and phosphate

Pyrite concentrations vary between 0.5 and 5.7% of the rock volume. Pyrite occurs in a range of forms and associations including framboids and euhedral crystals (Fig. 11a), as inclusions in a variety of cements (calcite, dolomite, feldspar and chert), in open pore space, within patched of organic matter, and between sheets of mica grains. All pyrite identified is interpreted to be authigenic, although some of the pyrite may be of detrital origin, based on the presence of clay coats on framboids (Fig. 11b).

Anhydrite concentrations are generally lower than 2% of the rock volume, but concentrations of up to 10% anhydrite were recorded in several samples. All anhydrite is authigenic and forms bedding-parallel poikilotopic cement (Fig. 11c) or is concentrated in nodules. It was not possible to distinguish different cement generations using SEM-CL due to the non-luminescent nature of anhydrite and lack of morphological differences between possible cement generations.

Phosphate concentrations are under 1 wt% in 90% of the samples. Phosphate occurs as phosphatized shell and shell debris (Fig. 10i), phosphatic nodules (Fig. 11d), grain coatings, or pore-filling cement. In addition, phosphate is also present as inclusions in dolomite and anhydrite cements (Fig. 11e). Although we considered all phosphate in our samples as authigenic, it is possible that some of the phosphate, particularly phosphate comprising shells and shell fragments is primary.

#### 450 **4.4.7 Organic matter**:

451 Total organic carbon content averages 1.2 wt%, with minimum and maximum values of 0.05 452 and 4 wt%, respectively. Organic matter concentrations show no consistent trend with depth, but

453 concentration generally decreases eastward toward the shallow basin. No primary (depositional) 454 macerals were identified in this study based on morphology, thus the organic matter in our 455 samples appears to be of secondary origin (i.e., bitumen or pyrobitumen). Organic matter fills 456 interparticle porosity between detrital and authigenic particles (Fig. 11a), as well as intraparticle 457 porosity in mica, pyrite, feldspars and dolomites (Fig. 11f).

#### 458 **4.5 Porosity, compaction, and Intergranular Volume (IGV)**

Matrix porosity from helium pycnometry ranges from 0.6 to 27.1 % with an average of 9.0 %. 459 The error reported for these measurements is under 6% for all samples, and most commonly 460 461 under 1.5%. Porosity reported from QEMSCAN analysis, which includes both open pores greater 462 than 4.8 µm and organic matter, varies between 0.2 and 22.7%. In contrast, open porosity 463 (primary and secondary porosity) estimated through point count analysis (Table 4) varies between 0.1 and 3.7%. No clear porosity-depth trends were observed with any method of porosity 464 measurement. Matrix porosity and QEMSCAN macroporosity values are presented in Fig. 12. 465 466 Matrix porosity (which includes micropores, mesopores and macropores) is consistently greater 467 than QEMSCAN porosity. Porosity measured by point counting is equal to or less than porosity measured by QEMSCAN, indicating that a large fraction of the pores is smaller than 4.8 µm, 468 469 although we note that the QEMSCAN macroporosity data also include large (> 4.8 um) pores 470 filled with organic matter. Secondary porosity (porosity generated through framework grain dissolution (Siebert et al., 1984; Harris, 1989) averages 4.2% of total porosity and only 0.2% of 471 472 bulk rock volume.

Evidence for mechanical compaction is present at the microscopic scale in the form of bent or broken mica grains (Fig. 9a, b), deformed clay clumps around detrital grain (Fig. 9c), and fractured detrital grains (Fig. 7i-I). To quantify mechanical compaction, we assess IGV<sub>m</sub> (Milliken and Olson, 2017) a modification of intergranular volume (IGV; Houseknecht, 1987; Paxton et al., 2002, among others) that is more appropriate for assessing compaction of mudrocks. IGV<sub>m</sub>

includes the residual primary porosity, cements, and pore-filling secondary organic matter. IGV<sub>m</sub>
values obtained from point count analysis are presented in Table 4.

With the exception of the sample from lithofacies K, samples from group one (on average, the 480 coarsest grained samples) have the highest IGV<sub>m</sub> values, whereas samples from groups two and 481 482 three have similar IGV<sub>m</sub> values (Table 4). However, it is important to bear in mind that the reported IGV<sub>m</sub> ranges may be heavily influenced by the limited number of samples associated with each 483 lithofacies. Samples from lithofacies group 1 (lithofacies B, M/N, and O) and group 2 (lithofacies 484 G/H) have similar IGV<sub>m</sub> values, ranging approximately between 28 and 50%. There are no 485 486 systematic differences in the IGV<sub>m</sub> values between different lithofacies or samples from different wells. The sample from well 9 has the lowest  $IGV_m$  value (31.1%), the samples from well 2 have 487 the highest average IGV<sub>m</sub> value (41%), and samples from well 4 have an intermediate IGV<sub>m</sub> value 488 (37.5%). 489

Evidence for chemical compaction (pressure-solution) is recorded in a large number of samples, affecting mostly silicate minerals. For the most part, pressure-solution features only penetrate cement rims of silicate minerals (Fig. 11a), and in fewer cases non-cemented detrital quartz grains (Fig. 11b) As overgrowths are commonly of variable thickness, even around a single grain, quantitative assessment of dissolved volumes is difficult.

# 495 4.6 Relative timing of diagenetic events

Our data from the Montney Formation represent a wide range of burial depths and organic matter maturities, but a few systematic differences in the nature and distribution of diagenetic phases with depth are expressed in our data set that can be used to differentiate the age and timing of events. Based on petrographic features such as cement overgrowths and crosscutting relationships, we divide diagenetic processes into pre-burial diagenesis and post-burial diagenesis. The paragenetic sequence for the formation is presented in Fig. 13 and described below.

#### 503 4.6.1 Pre-burial diagenetic events

Early or pre-burial diagenesis occurs at or very close to the sediment-water interface. Preburial diagenetic processes include dissolution of unstable aragonite/calcite shells (Fig. 10h), phosphatization of bioclasts (Fig. 10i), and growth of phosphatic nodules (Fig. 11d) and grain coats (Fig. 11e).

#### 508 4.6.2 Post-burial diagenetic events

Post-burial diagenetic events are largely characterized by mechanical compaction and massive cementation by carbonate and silicate minerals. The first cements to precipitate were the two generations of quartz (Fig. 7a), one generation of K-feldspar (Fig. 8a), one generation of Nafeldspar (Fig. 8b), and several generations of dolomite that include a final Fe-rich dolomite cement (Fig. 10b). Because no crosscutting or systematic overgrowth relationships were identified between the cement phases, we suggest they all precipitated relatively early (see discussion below) and approximately contemporaneously.

516 The earliest authigenic phases include guartz cement, non-ferroan dolomite cement, and feldspar cement and replacement, each surrounding a detrital core of the same mineral except 517 518 for K-feldspar, which locally overgrows plagioclase. Two generations of poikilotopic calcite cement 519 were identified, both precipitated around earlier authigenic phases (guartz, feldspars and 520 dolomite), (Fig. 10e). The first generation of calcite cement contains pyrite inclusions (Fig. 10g) 521 and thus postdates the formation of at least some of the pyrite. Calcite that replaces dolomite 522 (Fig. 10g) shares similar luminescence with the second generation of calcite cement, suggesting that both precipitated from a single fluid and are contemporaneous. 523

524 Much like calcite cement, anhydrite is poikilotopic, engulfing early authigenic phases (quartz, 525 feldspar, and dolomite), (Fig. 11c). None of our SEM-CL samples contained both anhydrite and 526 calcite, and we were unable to constrain the relative temporal relationship between these two

phases. However, as both calcite and anhydrite cements engulf and thus postdate quartz,
feldspar and dolomite cements, we interpret them as approximately contemporaneous.

529 Pressure solution penetrates cement rims of quartz and feldspars and were thus developed 530 after these cements precipitated (Fig. 14). However, the temporal relationship between pressure 531 solution and calcite and anhydrite cements based on petrographic evidence is unclear.

Pyrite occurs in numerous forms, as inclusions in different cements (calcite, dolomite, feldspar and chert), in open pore space (Fig. 7b), within patches of organic matter (Fig. 9b, d; Fig. 11a), and between sheets of mica grains. This suggests that pyrite formation was a recurring process that began shortly after deposition and ended, at the earliest, with the formation of calcite cement although crystal growth in open pores could have continued for much longer.

Residual hydrocarbons (bitumen and pyrobitumen) plug a large portion of the original interand intragranular pores, including secondary porosity that developed in cemented grains (Fig. 11a, f). This indicates that hydrocarbon emplacement postdated cementation of feldspars, quartz, dolomite, calcite and anhydrite and that grain dissolution either predated or was contemporaneous with the emplacement organic matter. In samples where secondary porosity is not filled with organic matter (Fig. 8f), this temporal relationship is less well constrained. Micropores developed in some of the organic matter in wells at high thermal maturity.

As suggested by the preservation of their delicate structure and their pore filling and/ or pore bridging nature, the last phases to crystalize in the Montney Formation are fibrous illite (Fig. 9f) and kaolinite clays (Fig. 9d), especially in the shallowly buried eastern wells (well 15 and well 16). Fibrous illite locally overgrows kaolinite, indicating that illite precipitation postdates the formation of kaolinite.

549 4.6.3 Unconstrained diagenetic events

550 Some diagenetic events lack clear evidence with regard to timing. Minor dissolution identified 551 in detrital chert (Fig. 7b), feldspars (Fig. 8b) and dolomite grains (Fig. 10b) is not well constrained.

Dissolution is restricted to detrital grains and does not occur in any of the cement overgrowths. Partial dissolution of detrital grains may be associated with pre-burial transport and weathering processes but could also be a post-depositional event. Similarly, we were not able to constrain the timing of albitization of detrital K-feldspar (Fig. 8d) and Na-feldspar grains (Fig. 8e). Finally, the relative timing of hydrocarbons migration/generation with respect to clay minerals precipitation is not entirely clear.

558 **5. Discussion** 

#### 559 **5.1 Grain size, sorting, and sediment transport mechanism**

560 Grain size and sorting can provide information about depositional processes and energy levels 561 of the transporting medium (commonly wind or water) at the site of deposition. The mean grain 562 size of samples from group one averages at 4.2  $\varphi$  (54  $\mu$ m) whereas mean grain size of samples from groups two and three averages at 5.0  $\varphi$  (31  $\mu$ m). The mode (most abundant grain size) 563 varies over a narrow range, between 4.4 - 4.8  $\varphi$  (36.7 and 46.3  $\mu$ m). Our observations are 564 consistent with Barber (2002) and Sanei et al. (2016), who also assessed grain size in the 565 566 Montney Formation through microscopy, but our modal values are slightly smaller than Davies et al. (1997), who reported that grain size varied between 3 and 4.6  $\varphi$  (40 to 120  $\mu$ m) with a majority 567 of the samples falling between 3.5 and 4  $\phi$  (62.5 - 88  $\mu$ m). 568

Our samples are moderately to poorly sorted (based on  $1\sigma$ , Table 2), whereas other studies 569 570 describe the Montney siltstone as moderately to well-sorted (Davies et al., 1997; Barber, 2002; 571 Sanei et al., 2016). Different grain size distribution (Davies et al., 1997) and sorting patterns (Davies et al., 1997; Barber, 2002) arise because prior studies relied largely on thin section 572 analysis and almost exclusively examined shoreface and turbidites facies within the Montney that 573 574 tend to be better sorted, whereas this study examined a wider range of lithofacies using high 575 resolution electron microscopy imaging. Sampling locations were not reported by Sanei et al. 576 (2016), making comparison to our results difficult.

577 Similar to Davies et al. (1997) and Barber (2002), we suggest that grain size distribution 578 indicates that sediments were introduced into the basin via a mixed traction and suspension 579 aeolian transport mechanism (Tsoar and Pye, 1987; Bullard and Livingstone, 2009; Nickling and Neumann, 2009). In this regard, the Montney siltstone is similar to other loess deposits (e.g., 580 581 Mason et al., 2003; Sun et al., 2006; Prins and Vriend, 2007; Crouvi et al., 2008; Nottebaum et 582 al., 2015), although the medium in which sediments were finally deposited was water. Zonneveld 583 and Moslow (2014; 2018) proposed a more complex array of transport processes, involving wind-584 blown material accumulation in fluvial channels of ephemeral rivers that drained into the basin 585 during flash floods. The authors, however, agreed that aeolian processes contributed significantly to sediment accumulation in the Montney Formation siltstone. 586

# 587 **5.2 Depth and time constraints on diagenetic processes**

Compaction and cementation act in combination to reduce the depositional porosity of the rock. However, while mechanical compaction acts to reduce IGV (or IGV<sub>m</sub> in mudrocks), cementation can preserve IGV or IGV<sub>m</sub> if cementation occurs before maximum compaction was achieved. Once formed and unless dissolution of cement occurs, cement volume remains unchanged with continuing burial. Thus, estimates of IGV<sub>m</sub> and cement volumes can constrain dominant mechanisms of porosity loss and the timing of cement formation, provided some knowledge of initial porosity is available.

Information on the depositional porosity of silt-size sediments is scarce. Hedberg (1926) and Chilingarian (1983) estimated initial porosities for siltstones to be between 50 and 80%. A compilation of porosities for silt-rich sediments (silt-size grain content of 60 to 90%) between 0 and 1700 m from the Ocean Drilling Program was reported by Kominz et al. (2011). In this dataset, depositional porosity of silt-rich sediment varies between 40 and 95%. However, within a few tens of meters of burial, porosity in most measurements is reduced to about 60%. We thus selected 60% as the depositional porosity for the Montney siltstone, similar to values of 53 to 57% assumed by Ness (2001) in a basin modeling study of several Montney wells. In the Kominz et al. (2011)
dataset, porosity for silt-rich sediments is well-constrained (more than one measurement in similar
depths) up to a depth of 1200 m (black curve, Fig. 15).

605 Calculations of IGV<sub>m</sub> and estimates of the timing of cement formation can be erroneous if 606 cements were dissolved. In the Montney Formation, however, there is little evidence for cement 607 dissolution, other than through pressure solution. From SEM-CL analysis, we established that 608 chemical compaction affected mostly overgrowths and was rarely documented to influence detrital 609 grains. Although it is difficult to quantify the effect of pressure solution, it is reasonable to assume 610 that chemical compaction made only a minor contribution to porosity reduction in the formation.

Minimum IGV<sub>m</sub> value (27.6%, sample 5V, well 4) can be used as a lower limit to the 611 depositional porosity of the sediment, and maximum  $IGV_m$  value (69.4%, sample 4V, well 4) can 612 613 be used as the upper limit of sediment porosity at the time of deposition. The IGV<sub>m</sub> of most 614 samples (14 of 17 samples) is between 31.1 and 51.9. All the samples were retrieved from depths larger than 2280 m (Table 4), but the high IGV<sub>m</sub> values of the samples suggest that compaction 615 ceased at a much shallower depth, ranging from 150 to 1100 m. Green arrows in Fig. 15 indicate 616 617 the cementation depths of three samples with IGV value of 52% (Fig. a), 40% (Fig. 15b) and 618 27.6% (Fig. 15c). Samples with  $IGV_m > 60\%$  could not be placed on the compaction curve. An IGV<sub>m</sub> value that is higher than the depositional porosity of the rock suggests that some of the 619 620 cement precipitated in pores previously occupied by detrital grains.

Depositional porosity of clean, well-sorted sands is approximately 45% (Paxton et al., 2002). Sandstones reach maximum compaction at about 2 to 2.5 Km, at which point porosity stabilizes at 26% and is not further reduced with additional burial (Paxton et al., 2002) (Fig. 15). The siltrich sediment of the Montney Formation is moderately to poorly sorted (Table 3), and it is possible that its initial porosity is lower than 60% and closer to that of sands. In this case, the siltstone compaction curve should shift closer to the sandstone compaction curve (blue curve in Fig. 15), which would result in shallower estimates of cementation depth for most of our samples. If depositional porosity was closer to 45%, this would also indicate that samples with IGV<sub>m</sub> values
larger than 45% have experienced some degree of detrital material dissolution.

IGV<sub>m</sub> can also be used to assess the relative effects of compaction (compactional porosity
 loss, COPL) and cementation (cementational porosity loss, CEPL) using equations 1 and 2
 (Ehrenberg, 1989):

633 (1) 
$$COPL = \phi_i - \frac{((100 - \phi_i) * IGV_m)}{100 - IGV_m}$$

634 (2) 
$$CEPL = (\phi_i - COPL) * \frac{C_m}{IGV_m}$$

Where  $\phi_i$  is the depositional porosity of the sediment, and  $C_m$  is the combined volume of 635 cement and secondary organic matter (bitumen) in primary pores (Milliken and Olson, 2017). 636 637 Assuming a depositional porosity of 60% in these calculations, cementation was responsible for 638 more porosity loss than compaction (CEPL > COPL; Table 4) in samples that were cemented at a very shallow depth (<300 m) and thus have preserved  $IGV_m$  values larger than 44%. Heavily 639 640 cemented samples are not unique to a single well, a single lithofacies, or a particular member of 641 the formation, making it difficult to identify an individual control for cementation in these samples. Compaction was responsible for most of the porosity loss in a majority of the samples (COPL 642 > CEPL). These samples were cemented at a greater depth (300 - 1100 m) and thus record 643 smaller IGV<sub>m</sub> values (27.6 - 40.6%). This suggests that the initial compaction rate of the siltstone 644 was very high, and only samples that were cemented within the top 300 m of the interval retained 645 high IGV<sub>m</sub> values. However, even samples with lower IGV<sub>m</sub> values were also cemented at a 646 relatively shallow depth (< 1100 m). The presence of reworked clasts containing dolomite cement 647 648 at the top of each Montney member (Davies et al., 2018) and low dolomite formation temperatures (<60°C) identified from fluid inclusion analyses (Davies et al., 1997) further support our 649 interpretation of cements precipitation at shallow burial depths. 650

Large volumes of cements together with indications for shallow cements precipitation suggest the existence of an open pore network that enabled massive fluid flow through the rock. Ness (2001) and Ducros et al. (2017) demonstrated through basin modeling that the Montney experienced slow burial for 100 million years following deposition, reaching a burial depth of about 1,500 m at the end of the Jurassic. We propose that shallow burial cementation occurred during this time period (Fig. 13).

# 657 5.3 Preburial and shallow burial diagenetic processes

In order to understand processes controlling dissolution and cementation at the sedimentwater interface and during very shallow burial, one needs to consider the environmental conditions under which the Montney siltstone was deposited. Early Triassic oceans were hot, acidic, and at least intermittently oxygen-depleted (Sobolev et al., 2011; Zonneveld, 2011; Sun et al., 2012; Clarkson et al., 2015; Kiehl and Shields, 2005). Worldwide ocean acidification began at the end of the Permian and extended into the Middle Triassic, caused by increased atmospheric CO<sub>2</sub> concentrations that originated from the Siberian Traps volcanic eruptions.

Elevated atmospheric CO<sub>2</sub> was also responsible for elevated surface ocean temperatures, 665 which exceeded 32°C near the equator (Sun et al., 2012) and 26°C at 30°N latitude (Kiehl and 666 Shields, 2005). Models show that ocean temperatures did not significantly diminish with depth, 667 668 leading to arrested oceanic circulation and widespread deep-water anoxia (Kiehl and Shields, 669 2005). Anoxic or dysoxic bottom water conditions are proposed for the time of the Montney 670 siltstone deposition, based on the presence of sulfide pseudomorphs of pollen grains and spores, the paucity of trace fossils, and concentration of redox-sensitive trace elements (U, V and Mo) 671 (Zonneveld et al., 2010; Crombez et al., 2017). Under acidic and reducing conditions, the 672 673 saturation limits in ocean water are high for alkaline elements such as sodium, potassium and calcium, as well as magnesium and iron (Tribovillard et al., 2006; Caracciolo et al., 2014). 674

# 675 **5.3.1 Calcite dissolution:**

676 The lack of detrital calcite in the Montney Formation can be attributed to global oceanic 677 acidification during the early Triassic (Sobolev et al., 2011; Zonneveld, 2011; Clarkson et al., 678 2015) and elevation of the calcite compensation depth (CCD) to shallow marine settings (Playter, 2013). Acids released by decaying organic matter (Wallmann et al., 2008) or the presence of 679 680 unstable aragonitic precursors may have also contributed. Dissolution processes may also have formed the small dissolution pits observed in many of the detrital minerals (mainly feldspars, 681 682 dolomite, and chert), although these features may also be related to grain weathering during 683 sediment transport.

684 5.3.2 Feldspars and dolomite cementation

We suggest that pH stabilized shortly after deposition through mineral dissolution that released alkali elements into the pore water. The increased alkalinity was expressed through the precipitation of feldspars and dolomite cements, as well pyrite and iron-rich dolomite, indicating a decrease in the solubility of the dissolved alkali elements (Tribovillard et al., 2006; Caracciolo et al., 2014).

690 Dolomitization models, specifically the evaporative-brine refluxing model (Saller and Henderson, 1998 and reference therein; Warren, 2000; Machel, 2004) may apply to the Montney 691 692 Formation. This model, proposed originally by Adams and Rhodes (1960) and documented in 693 ancient and modern platforms and ramps worldwide (Saller and Henderson, 1998; Warren, 2000; Machel, 2004), provides a mechanism for fluxing large volumes of water through shallowly buried 694 695 sediment. According to this model, dense hypersaline brines, saturated with calcium and magnesium. form in lagoons through evaporation and sink downward through the underlying rock 696 where dolomite precipitates due to retrograde solubility (Warren, 2000; Jones and Xiao, 2005). 697

The reflux model provides an explanation for the large volumes of early cement in the Montney Formation, in particular the dolomite cement that comprises 12% of the rock volume. We postulate that an evaporative lagoon existed on the updip margin of the basin, where dense saline brines

701 formed and migrated downward and basinward, following permeable pathways, Although the 702 updip portion of the Montney Formation was eroded during the Late Cretaceous Laramide 703 Orogeny (Edwards et al., 1994; Davies et al., 1997, Moslow, 2000), the presence of an 704 evaporative lagoon is consistent with our understanding of Early Triassic climate for the area, 705 which is inferred to have been arid based on the presence of aeolian dunes, palynomorphs, 706 regionally extensive anhydrite and reworked anhydrite nodules in the Montney Formation and the 707 age-equivalent Sulphur Mountain Formation (Zonneveld and Moslow, 2018 and reference 708 therein). The saline brines, which would have originated from seawater, possibly mixed with some fraction of hydrothermal fluids (Liseroudi et al. 2020), advected the solutes responsible for the 709 massive precipitation of quartz, feldspars, calcite, dolomite, ferroan-dolomite, pyrite, and 710 711 anhydrite cements that account for over 30% of the rock mass in the Montney siltstone (Table 4). 712 Evaporated seawater also contains elevated concentration of sodium and potassium. We 713 propose that the dolomitizing fluids also carried sufficient sodium to precipitate Na-feldspar cements and enable albitization, in accordance with models proposed by Kalsbeek (1992) and 714 715 González-Acebrón et al. (2010). Increased potassium concentrations in evaporated seawater, 716 together with potassium released by albitization of K-feldspar (Fig. 8d) would have provided 717 solutes for the precipitation of K-feldspar cement.

#### 718 **5.3.3 Quartz:**

The precipitation of large volumes of quartz cement is commonly considered to be triggered by temperature-dependent reactions that occur during deep burial (for example: McBride, 1989; Walderhaug, 1994; Giles et al., 2000). However, high IGV values, together with overgrowth relationships that indicate quartz cement preceded calcite cement, indicate shallow cementation. Total quartz cement concentration (first and second generations) varies between 3.5 and 11.6%, with an average of 7.4% (Table 4). Shallow (1-2 Km) quartz cementation of such volumes is documented in reservoirs world-wide (Fisher et al., 2000; Giles et al., 2000; Hartmann et al., 2000)

and attributed to feldspar dissolution, reprecipitation of dissolved siliceous skeletal grains,
 pressure solution, and precipitation from silica-saturated meteoric water (McBride, 1989 and
 reference therein; Giles et al., 2000; Worden and Morad, 2000 and reference therein).

The solubility of silica in water is very low (Williams et al., 1985 and reference therein), and improbably high volumes of water would be required to supply enough silica to precipitate the volumes of quartz cement in the Montney (Worden and Morad, 2000). There is also no indication of silica influx from neighboring mudrocks in the form of increased quartz cementation towards the top or bottom edges of the Montney. Therefore, an internal silica source for quartz cement is favored. We suggest that several internal sources combined to provide silica for the two generations of quartz cement.

Some silica was provided through in-situ dissolution and/or recrystallization of chert, although 736 737 this cannot account by itself for the volumes of quartz cement in the samples. Dissolution of chert 738 grains is readily identified through SEM imaging (Fig. 7c), and evidence for chert recrystallization is in the form of intact, euhedral quartz grains that retained some of the mottled luminescence 739 740 texture of chert (Fig. 7b). Angular holes identified on the surface of guartz overgrowth (Fig. 7h) 741 suggest the incomplete recrystallization of chert to quartz (see Hattori et al.'s (2003) study of the 742 Miocene Kunimi Formation in Japan). Alternatively, the angular cavities in chert grains and 743 dissolution porosity in chert may reflect decalcification of the chert (tripolitic chert; Manger, 2014). Silt-size guartz grains themselves may have been another potential source for the guartz 744 745 cement. The structure of all quartz crystals terminates in a thin layer (~100 nm) of amorphous 746 silica (Cecil, 2004) that is much more soluble than quartz (Aase at al., 1996) and can become an important source for silica (Cecil, 2004). Experiments on mechanically abraded quartz grains 747 demonstrated that the lattice structure of quartz is distorted to a depth of at least 15 µm, rendering 748 749 the outer section of the grain metastable and relatively soluble (Cecil, 2004 and references 750 therein). These experiments suggest that silt-size quartz grains deposited by aeolian processes,

particularly very small grains (2-3 microns) are highly reactive and can be easily dissolved, which
 suggests that the original detrital composition may have been more quartz-rich than at present.

753 Another fraction of the quartz cement may have been be sourced from biogenic silica. Reports of biogenic silica in the Montney Formation are rare. Zelazny et al. (2018) hypothesized that chert 754 755 in the time-equivalent Sulphur Mountain Formation in Alberta resulted from recrystallization of 756 concentrations of radiolarian and/or sponge spicules. In mudrocks, excess of silicon relative to 757 aluminum indicates the presence of biogenic silica (Tribovillard et al., 2006; Ross and Bustin, 758 2009). Wüst et al. (2018) suggested that biogenic silica is an important component in at least 2 759 intervals within the Montney Formation in Alberta, based on Al/Si ratios and results from principal component analysis. However, whole rock concentrations of both aluminum and silicon in the 760 Montney Formation are affected by the presence of large amounts of guartz and feldspars 761 762 cements and authigenic clays, and in this case, increased ratio between silicon and aluminum 763 cannot be easily used to indicate the presence of biogenic silica.

Our petrographic observations suggest that a small amount of biogenic silica is preserved in the Montney Formation in the form of silica nanospheres (Fig. 7g), interpreted to be the product of bacterial activity (Al Rajaibi et al., 2015; Milliken and Olson, 2017; Longman et al., 2019), and possible remnants of agglutinated foraminifera (Fig. 7d). Silica nanosphere cement is difficult to identify in polished Montney samples, but examination of freshly exposed surfaces under the SEM indicates that it is a minor type of silica cement. It is possible, however, that some of the biogenic silica was dissolved and incorporated into one of the generations of quartz cements.

The illitization of smectite (discussed below) also would have released large amounts of silica (Hower et al., 1976; Boles and Franks, 1979), which may have contributed to the first generation of quartz cement. Mass balance calculations assuming an initial composition of 20% smectite (appendix 2) show that illitization of smectite would have contributed 5-20% of the silica composing the first quartz cement generation.

Finally, some of the quartz cement originated from pressure solution (Fig. 7b, Fig. 14). Pressure solution is generally associated with high temperatures during deep burial (Walderhaug, 1994; Bloch et al., 2002), but other studies (summarized by Makowitz and Milliken, 2003) suggest that quartz dissolution is enhanced, even at low temperatures, by the presence of fractures close to the dissolution front in quartz grains. However, we did not identify a clear relationship between quartz microfractures and the presence of pressure solution.

782 Quartz cement volumes vary over a wide range (2 to 11 wt%) for samples with average grain 783 sizes  $< 20 \,\mu\text{m}$ . Samples with coarser grain size usually have larger cement volumes (5-12 wt%) 784 (Fig. 16a). We propose that a major control on quartz cementation is the abundance of detrital clay coatings on detrital quartz grains (Fig. 7c, 9c), which inhibit quartz cementation by blocking 785 nucleation cites (Heald and Larese, 1974; Wilson, 1992). Needham et al. (2005) demonstrated 786 787 that clay coats can be generated through digestive processes of worms. Lithofacies in group one 788 have the highest bioturbation index (Table 2) and are thus more likely to have clay coats and consequently lower quartz cement volume. It is worth noting, however, that the presence of clay 789 790 coats is not directly related to clay abundance. Group one samples have the lowest amount of 791 total clay and high quartz cement volume, while samples from group three have higher total clay concentration but similarly high quartz cement volume. (Fig. 16b). 792

# 793 **5.3.4 Pyrite**

Pyrite framboids form under euxinic conditions, either in the water column or below the watersediment interface (Wilkin et al., 1996; Wilkin and Barnes, 1997; Wignall and Newton, 1998). Berner (1984) and Wilkin et al. (1996) demonstrated that framboids growing in a euxinic water column are generally <6  $\mu$ m and are more uniform in size than framboids growing in sediment, whereas crystalline pyrite is thought to develop only within the sediment itself. The wide size variation in pyrite framboids observed in our samples, together with the presence of crystalline pyrite suggest that pyrite precipitation occurred mostly within the sediment rather than in the water

column. Pyrite precipitation requires both iron and sulfur to be available in the pore water. Based
on sulfur and oxygen isotopic composition, Liseroudi et al. (2020) postulated that a sulfur-rich fluid
derived from a mix of Triassic seawater, brines sourced from Devonian evaporites in the WCSB,
and in-situ anhydrite dissolution was present in the porewater of the siltstone.

805 5.3.5 Calcite and anhydrite cementation

Sources for calcite cement in the Montney are unclear but it has been postulated to be derived 806 807 from carbonate dissolution in the underlying Permian strata (Nassichuk, 2000), possibly due to hydrothermal fluid involvement (Liseroudi et al., 2020). Our petrographic observations 808 809 demonstrate only one generation of anhydrite cement, although Liseroudi et al. (2020) identified 810 two generations of anhydrite in the Montney Formation based on sulfur isotopic compositions. 811 Consistent with our observations, Davies et al. (1997) and Liseroudi et al. (2020) attributed all of 812 the anhydrite cementation to early diagenesis (shallow diagenesis in this study). Based on sulfur and oxygen isotopic compositions, Liseroudi et al. (2020) suggested that the first anhydrite 813 cement precipitated directly from Triassic seawater, whereas the later generation shows 814 815 compositional similarities to underlying Devonian evaporites.

#### 816 **5.3.6 Illitization and albitization:**

817 Compositional variations of MLIS clays in the Montney Formation provide additional 818 information about the diagenetic evolution of the siltstone. Our QEMSCAN analysis results indicate that the major clay species in the Montney Formation are illite and MLIS (70-98% of total 819 clay content), and quantitative XRD analysis determined MLIS composition to be illite (95)/ 820 821 smectite (5) with insignificant swelling potential throughout most of the basin. Reports of swelling clays in the Montney are limited to the Ring-Border and Dixonville fields (Fig. 1) at the 822 northeastern margin of the formation (Edwards et al., 1994; Zonneveld and Moslow, 2014, 2018). 823 824 Quantitative XRD analysis of three samples taken from the Dixonville field (well 16, Fig. 1) confirmed the presence of MLIS with approximately 20% swelling layers (illite (80)/ smectite (20)). 825

SEM examination of freshly exposed surfaces indicated that all the clays in those samples (other than kaolinite) have a detrital morphology and although they may have been chemically altered from a detrital precursor, they did not precipitate in situ.

829 The occurrence of slightly swelling clays geographically near and at similar burial depth to 830 occurrences of non-swelling clays indicates that reduction of swelling potential (conversion 831 smectite to illite) of the clays in the Montney does not result from high temperatures (>90 °C), as 832 has been convincingly demonstrated for illitization of smectite in the Gulf of Mexico (Hower et al., 833 1976; Boles and Franks, 1979). As it is unlikely that the Ring-Border and Dixonville deltas (Fig. 834 1) had a different sediment source than the rest of the formation, a different model for illitization of smectite is required. We suggest that this process was a time-dependent, low temperature 835 reaction, taking place at temperatures of 60-80°C, over extended period of time (10<sup>8</sup> years). Such 836 837 a process would have required sufficient permeability to allow large volumes of water to interact 838 with the rock (Buatier, 1992; Kirsimäe et al., 1999; Moore, 2000). We propose that partially illitized detrital MLIS clays were deposited as dispersed material between other matrix components. The 839 840 MLIS clays were further illitized to their current composition [illite (95)/ smectite (5)] over 100 841 million years following deposition, as the Montney was slowly buried to a maximum depth of 842 ~1500 m. Prolonged shallow burial maintained high porosity and permeability in the siltstone, 843 allowing large volumes of fluid to pass through the formation and interact with the available MLIS. The illitization of smectite consumes potassium. Mass balance calculations based on point 844 845 count results (appendix 2) show that albitization (replacement of K-feldspar by Na-feldspar) would 846 have released sufficient potassium to illitize all MLIS clays in the Montney to their present-day composition, similar to models developed for a number of other settings (Hower et al., 1976; 847 Morad and Aldahan, 1987; Saigal et al., 1988; Aagaard et al., 1990). Post-burial K-feldspar and 848 849 mica dissolution may have also contributed potassium (Moore, 2000).

For the most part, clays in the Montney Formation are dispersed within the matrix of hard grains. The slightly swelling clays [illite (80)/ smectite (20)] in the Dixonville and Ring Border deltas

however were deposited mostly in several cm thick beds. The lower permeability of these beds
restricted fluid flow and thus potassium supply and led to the preservation of some swelling
potential in these clays.

855 5.3.7 Organic matter

The origin of organic matter in the Montney, whether primary (i.e., present in the siltstone at the time of deposition) or the result of hydrocarbons migration, is still vigorously debated. Movement of liquid hydrocarbon within the siltstone is recorded by flow structure preserved in solid pyrobitumen (Chalmers and Bustin, 2012; Akai and Wood, 2014; Sanei et al., 2015; Wood et al., 2015; Wood et al., 2018), but these observations have no bearing on the source of the liquid hydrocarbons.

862 Some oil-to-source correlation studies concluded that oil migrated into the Montney from the overlying Doig, Nordegg, and the Exshaw Formations (Riediger et al., 1990; Chatellier et al., 863 2018; Feng et al., 2016) but others suggest that at least some hydrocarbons were generated in 864 865 the western section of the Montney Formation (Feng et al., 2016; Feng, personal communication). 866 However, depositional macerals have never been reported from this deeply buried western section of the formation, possibly because of the high maturity that makes it is extremely difficult 867 868 to distinguish pyrobitumen from kerogen, if the latter is present in the rock (Lewan and Kotarba, 869 2014).

The presence of depositional macerals and remnant generation potential are also disputed. Sanei et al. (2015) and Wood et al. (2018) noted the absence of primary macerals from their samples, which varied in maturity (Ro% 0.93 to 2.08), and Sanei et al. (2015) indicated that fewer than 10% of samples examined still have some generation potential. On the other hand, Romero-Sarmiento et al. (2016) established the presence of vitrinite and liptinite in immature Montney samples, and there are several reports of good to very good generation potential for samples with immature and early mature organic matter from the Montney (Ibrahimbas and Riediger, 2004;
Ejezie, 2007; Chalmers and Bustin, 2012; Feng et al., 2016; Chatellier et al., 2018) that indicate
the presence of non-spent organic matter.

We did not identify any depositional macerals in our samples, and all the organic matter is considered secondary in origin (i.e., migrated hydrocarbons). The massive cementation documented in our study require that large volumes of water-bearing solutes flow through the siltstone, and it is difficult to envision that marine organic matter will be preserved under such conditions. It is possible that primary organic matter was preserved in very fine-grained intervals, where flow was restricted.

### 885 5.4 Late shallow burial diagenesis (eastern subcrop)

886 Late diagenesis in the eastern section of the Montney Formation, particularly near the subcrop 887 edge (wells 15 and 16, Fig. 1), is characterized by meteoric water influence at shallow depth. The effect of meteoric water is evident by the precipitation of kaolinite (Fig. 9e) and massive 888 overgrowths of quartz (Fig. 7e) and K-feldspar, together with extensive dissolution of dolomite 889 890 (Fig. 10d). We lack quantitative data to assess the degree of cement development for the shallow 891 Montney wells (wells 15 and 16), but QEMSCAN data show an increase in kaolinite for wells 11 and 15, demonstrating the effect of meteoric water on the erosional edge of the subcrop. Similar 892 893 observations were reported for the subcrop edge of the Brent Formation of the North Sea 894 (Osborne et al., 1994).

## 895 **5.5 Composition and grain size dependency of lithofacies**

The diagenetic pathway of a rock may be linked to its depositional environment through variation in grain size and detrital composition. Grain size and composition dictate both the initial porosity and permeability of a rock (Morad et al., 2010) and its compaction rate, thus controlling available pore space for cementation and fluid-flow, while mineralogy and grain size influence chemical reactivity during diagenesis. Here we examine the relationships between lithofacies in

the Montney Formation, grain size and detrital mineralogical composition. In addition, we consider
 the effects of diagenetic processes on the overall mineralogical composition of the lithofacies.

903 Bulk rock compositions and calculated average detrital compositions for seven lithofacies from 904 three cores are presented in figure 6b. Detrital compositions were calculated by subtracting the 905 percentage of cement (obtained from point count analysis) from the total content of each phase (obtained from QEMSCAN analysis). For example, lithofacies F in well two has an average of 906 907 39.2 wt% of quartz. Point count analyses (Table 4) demonstrated that 28.8% of the quartz in this 908 facies is authigenic, while 71.2% of the guartz is detrital. The detrital guartz content for lithofacies F in well 2 is therefore 27.9 wt%. Figure 6b demonstrates that carbonate minerals exhibit the 909 largest differences between present-day mineralogical composition and calculated detrital 910 composition. 911

In terms of present-day mineralogy (Fig. 6b), lithofacies are compositionally indistinct from one another with the exception of the easternmost well (well 15). We propose that the present homogeneity is explained by little variability in the composition of deposited detrital material and the large volume of cements that precipitated during shallow burial diagenesis. These cements, which account for more than 30% of present-day rock volume (Table 4), overprinted small compositional differences in detrital grain composition between the different lithofacies in the rock.

# 918 5.6 Implications of diagenesis for reservoir quality

919 It is important to consider how diagenetic processes influence porosity and relative 920 permeability, key parameters that describe reservoir quality. Locally (primarily in areas near the 921 erosional edge of the formation), dissolution can be an important porosity-generating mechanism, 922 but dissolution is generally a minor phenomenon in the Montney Formation and will not be 923 discussed further.

924 Cementation and compaction acted together to reduced porosity and permeability in the 925 Montney Formation, as discussed in section 5.2. Ghanizadeh et al. (2015) and Sanei et al. (2016)

926 qualitatively associated volumes of carbonate cement with grain size. The authors suggested that 927 coarser sediments retained higher porosity and permeability during earlier burial and allowed 928 higher fluid flow and larger fluxes of cementing components. Both Ghanizadeh et al. (2015) and 929 Sanei et al. (2016) referred to present day apparent grain size, which includes detrital grains and 930 cement overgrowths rather than the detrital grains present at the time of dolomite cement 931 precipitation.

932 We examined relationships between detrital quartz grain size (calculated using the equation 933 presented in Appendix 3) and cement volumes in three wells in the study area. To calculate 934 cements volumes, we assumed that average cements volumes identified in point count analysis are representative for the formation. Cement volumes were calculated from QEMSCAN analyses 935 for each lithofacies in each well and the relative percentage of each cement, obtained from point-936 937 count analyses. For example, point count analyses results show that dolomite cement is 53% of 938 the total dolomite for lithofacies G/H in well 2 (Table 4). Therefore, 53% of the dolomite identified in QEMSCAN analysis for all samples of lithofacies G/H in well 2 was estimated to be authigenic. 939 Results of these calculations are presented in figure 16 (closed symbols) together with the 940 941 point count analysis results (open symbols). Note that the calculated volumes of quartz cement 942 fit reasonably well within the error of the measured data from point count analysis. No clear distinction between samples from different lithofacies groups exist in any of the graphs in Fig. 16, 943 although it is possible that the large error associated with the measured detrital grain size (not 944 depicted in the figure) may mask these relationships. Fig. 16 demonstrate that no positive 945 946 correlation exists between detrital quartz grain size and total cement volume (Fig. 16 c) or calcite cement volume (Fig. 16 d) in our samples. In fact, most samples from group one, which are the 947 948 coarser samples, have little to no calcite cement.

Our observations are consistent with findings of Chalmers and Bustin (2012) that calcite cement is responsible for much of the porosity destruction in the Montney Formation (Vaisblat, 2020). In addition, we recognize that organic matter emplacement dramatically reduced porosity

in the Montney Formation and agree with the conclusion of Wood et al. (2015) that there is no
statistically significant correlation between porosity and TOC on a regional scale.

### 954 5.7 Are siltstones unique?

A comparison of compaction curves for sandstones, siltstones and mudstones (Fig. 15) demonstrates that the compaction rate of clastic sediments in the upper 1.5 Km diminishes with increasing grain size. At depth > 1Km, a siltstone retains higher porosity and permeability than the finer grained mudstone.

The influences of grain size on chemical diagenesis are complex. Finer grained rocks provide 959 larger surface area of detrital minerals per unit volume, increasing the amount of nucleation sites 960 for quartz, feldspar and dolomite cementation and resulting in larger cement volumes (Ben Baccar 961 962 et al., 1993; Walderhaug, 1994, 1996; Lander and Walderhaug, 1999). On the other hand, 963 experiments demonstrated that quartz cement crystallization rates decrease considerably when euhedral faces develop, which happens faster when the cores of detrital grains are small (Lander 964 et al., 2008). Our observations suggest that the large surface area available for cementation in 965 966 the Montney siltstone, combined with slower initial compaction rate (compared to clay-rich 967 mudstones) and a prolonged shallow burial allowed for enough time for quartz cement growth in 968 spite of the slow cementation rate. The prolonged shallow burial also allowed for sufficient flux of 969 fluids transporting solute that precipitated feldspar and carbonate cements. Thus, in certain burial 970 history scenarios, siltstones may be more prone to early massive cementation than sandstones 971 and mudstones.

The Montney Formation siltstone contains equal or lower amounts of clay and carbonate minerals and more quartz and feldspar than other well-described fine-grained sediments (Fig. 17), (with the exception of the Barnett and Woodford mudstones, where much of the silica is of biogenic origin (Milliken et al., 2007; Dong and Harris, 2020). It is important to note that almost all studies of mudstone diagenesis do not report grain size distribution, making the comparison

between the Montney siltstone and other mudrocks difficult. However, it is possible to compare the abundance of hard grains (quartz and feldspar) and soft, malleable components (clays and organic matter) between the two mudstones types. This comparison shows that the Montney siltstone contains less clays and more hard grains than most mudrocks (Fig. 17).

Our study of the Montney Formation illustrates that a fundamental difference between mudrocks and siltstones is the nature of the rock framework. Mudrocks are matrix-supported, in which silt grains 'float' in an organic matter- and clay-rich matrix. In contrast, the Montney siltstone has a hard grain, cement-supported framework. This difference affects compaction and thus fluid flow during early burial. The resulting diagenesis leads in turn to different reservoir and geomechanical properties.

### 987 6. Conclusions

Our results demonstrate both significant similarities and important differences between the diagenetic evolution of the Montney Formation, predominantly a siltstone, and that of sandstones and shales. Like shale formations, the Montney underwent substantial modification at relatively shallow burial depth, but unlike shales, this modification was largely the result of massive import of diagenetic components. Like sandstones, cementation of an open grain framework was significant, but unlike most sandstones, the components were derived from external rather than internal sources.

We demonstrate that most of the diagenetic processes affecting the Montney Formation occurred during shallow burial (less than 1100 m). Precipitation of massive amounts of cements at shallow burial depth including quartz, calcite and dolomite, overprinted minor depositional variability in composition between the different lithofacies in the rock. The massive amounts of shallow burial cement were related to brine reflux from updip (now eroded) parts of the Montney depositional system. This hydrologic drive, combined with an open pore system, allowed for largescale transport of chemical components into the formation.

In the Montney Formation, and possibly in other siltstones, deep burial diagenesis plays only a minor role in the compositional evolution of the rock and appears to be limited to precipitation of fibrous illite and, possibly, to pressure solution and the precipitation of a late, secondary quartz cement phase. The limited variability of grain size and the relatively homogeneous detrital composition largely constrained diagenetic pathways, although we attribute the massive cementation to reflux of saline brines from updip lagoons, a consequence of deposition setting.

Finally, we demonstrated that the framework of silt-rich mudrocks (siltstones) differs fundamentally from that of clay-rich mudrocks (shales). Clay-rich mudrocks are fine-matrixsupported whereas the Montney siltstone has a hard-grain and cement-supported framework that was resistant to compaction, leading to different diagenetic pathways between the two rock types, and thus different porosity and permeability and different geomechanical properties.

## 1013 Acknowledgments

The authors acknowledge NSERC (CRDPJ 462381 - 2013) and Energi Simulation Research Consortia in Reservoir Geomechanics for their financial support to the Reservoir Geomechanics Research Group (RG)<sup>2</sup> at the University of Alberta. We would also like to acknowledge SGS Canada for providing QEMSCAN analysis and interpretations used in this work. In addition, we thank Dr. Brian Jones, Dr. Stephen Hillier, and Dr. Eric Eslinger for their suggestions and advice in preparing this paper.

### 8. Figure caption

1468 Fig. 1: A map of the Montney Formation in Alberta and British Columbia. Insert shows the 1469 location of the Montney Formation in the Western Canada Sedimentary basin. Green Arrows 1470 show inferred directions of sediments transport into the basin. Arrow size indicates the relative 1471 importance of the sediment source. Most of the sediments were sourced from the northwestern 1472 Margin of Laurentia, positioned to the east (arrow 1). Smaller amounts of sediment came from the Inuitian orogenic wedge and the Yukon-Tanana accretionary terrain to the north (arrow 2), 1473 1474 and from the Meosin-Muinok High to the southwest (arrow 3). A potential minor western 1475 sediment source (arrow 4) was also postulated. Most of the updip section of the Formation was eroded, but two deltas are preserved (yellow). Hexagons show location of study wells. Color-1476 1477 coding relates to the dataset obtained from the wells (see table 1 for more details). Full dataset 1478 includes core description, SEM and SEM-CL imaging, thin section analysis, QEMSCAN analysis 1479 on rock chips, porosity, and TOC. Map modified after Zonneveld and Moslow (2018).

Fig. 2: A chronostratigraphic chart for the Lower Triassic Montney Formation. The location
of wells where mineralogy data was obtained for is marked at the top of the chart. UC is
unconformity. Ages after Golding et al., 2016.

**Fig. 3:** Representative photograph of lithofacies identified in the four Montney Formation

1484 cores. (a) Lithofacies A - interlaminated siltstone and sandstone with current ripples. (b)

1485 Lithofacies B - massive to convolute bedded Massive sandy siltstone with carbonate

1486 concentration (in white). (c) Lithofacies C - bioturbated clay-rich siltstone. (d) Lithofacies D -

1487 mudstone with Horizontal parallel lamination (sections where lithofacies D is present are marked

- by arrows). (e) Lithofacies E dolomitic siltstone. (f) Lithofacies F faintly laminated calcareous
- siltstone. Arrows point to faint laminations). (g) Lithofacies G/H laminated siltstone. (h)

1490 Lithofacies I - horizontal to irregularly laminated calcareous siltstone. (i) Lithofacies J - massive

1491 siliceous clayey siltstone. (j) Lithofacies K - massive siliceous clayey siltstone. (k) Lithofacies I -

siliceous phosphatic siltstone with phosphate nodules (highlighted in white). (I) Lithofacies M/N bioturbated, calcareous, sandy siltstone. (m) Lithofacies O - hummocky to ripple cross-stratified
sandy siltstone. (n) Lithofacies P - interbedded siliceous-mudstone and calcareous- siltstone.
CR - current ripple, PL- planar lamination, B - burrow, PH - phosphate, TS - truncation surface.

**Fig. 4:** Cumulative grain size distribution in phi ( $\varphi$ ) units, for all lithofacies identified in the study. Black line is the average cumulative grain size for the lithofacies. Gray area shows grain size range for all samples taken from the lithofacies. No samples were obtained from lithofacies D (mudstone). Lithofacies F (faintly laminated calcareous siltstone) is the only lithofacies where a significant difference in grain size distribution exists between samples taken from different cores.

1502 Fig. 5: Grain size distribution of all 14 lithofacies identified in wells 2, 4, 9, and 15. (a) Group 1503 1, mixed siltstone-sandstone lithologies (sand commonly >10%). Samples in this group have 1504 sedimentary structures indicative of higher water energy in the depositional environment such as current ripples, hummocky cross stratification, and rip-up clasts. (b) Group 2, siltstone with 1505 1506 up to 10% sand. Samples in this group are commonly laminated. (c) Group 3, siltstone with up 1507 to 5% sand. With the exception of lithofacies P, samples in this group are massive in 1508 appearance. Letters (blue) mark the classification fields denoted by Macquaker and Adams 1509 (2003), where [a] is silt-dominated mudstone, [b] silt-rich mudstone, [c] sand-bearing, silt-rich mudstone, [d] sand and clay-bearing, silt-rich mudstone, [e] clay-bearing, silt-rich mudstone, 1510 1511 and [m] sand and silt-bearing mudstone.

Fig. 6: QEMSCAN analysis results in wt%. QFM is the sum of quartz, K-feldspar, Nafeldspar and micaceous minerals. Clay minerals include MLIS and kaolinite, and carbonate minerals include calcite, dolomite and Fe-rich dolomite. Compositional variations between samples of different groups (a) and different lithofacies (b) are presented for the four Montney cores logged. Note the large variations in the content of carbonate minerals between samples in

all wells. Plus symbols in (b) are calculated detrital composition for several lithofacies. With the
exception of well 15, lithofacies from group one have the lowest clay content. With the exception
of well 15, different lithofacies and different lithofacies groups are compositionally indistinct from
one another.

1521 Fig. 7: Quartz in the Montney Formation (a) SEM CL image of detrital guartz grains (Qd). 1522 blue luminescent early quartz cement (Qc1), and red luminescent late quartz cement (Qc2); 1523 Sample 3B, well 9, 3340 m. (b) SEM-CL image of a chert fragment (Crt) with spongy texture and 1524 mottled blue and red luminescence. Note concave-convex contact of pressure solution (PS) 1525 between chert fragment and adjacent detrital quartz grain; sample 2H, well 4, 2664m. (c) SEM-1526 EDS image of chert (Crt) with spongy texture and abundant porosity. Sample 2AE, well 4, 2621 1527 m. (d) SEM-EDS image of agglutinated foraminifera. Sample 1AE, well 15, 864.9 m. (e) SEM-1528 SE image of massive quartz cement overgrowth (Qog). Note clay coats inhibiting quartz 1529 cementation (white arrow), sample 1S, well 15, 876.9 m. (f) SEM-SE image of euhedral microcrystalline quartz cement (Qmc). Note lack of cement adjacent grains, where detrital clay 1530 1531 coats are present (white arrow). (g) SEM-SE of Silica nanospheres, sample 20A, well 2, 2530 m.(h) SEM-SE image of recrystallized chert (R-Crt). Incomplete transformation of chert to quartz 1532 1533 created holes on the face of a quartz crystal, sample 10, well 1, 2028m. (i) SEM-CL image of a 1534 fractured detrital quartz grain. Fractures are filled with blue-luminescing cement. Sample 5K, 1535 well 9, 3379 m. (j) SEM-CL image of a fractured detrital quartz grain. Fractures are filled with 1536 red-luminescing cement. Sample 3E, well 2, 2281 m. (k) SEM-CL image of fractured blue-1537 luminescing cement. Fractures are filled with red-luminescing cement. Sample 4P, well 2, 2289 m. (I) Shattered detrital quartz cement. Many fractures are filled with red-luminescing cement. 1538 Shattered grains are rare. Sample 2AQ, well 9, 3289 m. 1539

1540 Fig. 8: Feldspars in the Montney Formation. (a) SEM-EDS image (left) and SEM-CL image
1541 (right) of highly luminescent detrital K-feldspar (K-frd) surrounded by a rim of non-luminescent

1542 K-feldspar cement (K-frc), sample 4F, well 9, 3364m, (h) SEB-SE image of K-feldspar and 1543 quartz overgrowth, sample 1S, well 15, 878.5 m. (b) SEM-EDS image (left) and SEM-CL image 1544 (right) showing detrital Na-feldspar (Na-frd) and Na feldspar cement (Na-frc). Note the straight 1545 edges of the cement, sample 4F, well 9, 3364m. (c) SEM-EDS image showing discrete euhedral 1546 K-feldspar crystals (white arrows), sample 1AE, well 15, 864.9m. (d) SEM-EDS image (left), SEM BSC (center), and SEM-CL image (right) of luminescent detrital K-feldspar (K-frd) and 1547 1548 non-luminescent authigenic Na-feldspar replacing the detrital grain (Na-frr), sample 2AQ, well 4, 1549 3289.05 m. (e) SEM-EDS image (left) and SEM-CL image (right) of highly luminescent detrital 1550 Na-feldspar (Na-frd) and non-luminescent authigenic Na-feldspar replacing the detrital grain (Na-frr). Note K-feldspar cement (K-frc) overgrowing Na-feldspar, sample 1C, well 9, 3278m. (f) 1551 SEM-EDS image of dissolution at the boundary between detrital grain and cement rim of K-1552 1553 feldspar, sample 1C, well 9, 3278m.

1554 Fig. 9: Mica and clay minerals in the Montney Formation. (a) SEM-EDS image of chlorite (Mg-rich mica). Note split grain edges, sample 16I, well 2, 2487m. (b) SEM-BS image of 1555 1556 deformed (green arrow) and dissolved (yellow arrow) mica grain, sample 10D, well 2, 2396 m. 1557 (c) SEM-SE image of detrital clay coats around a detrital quartz grain, sample, 7C, well 2, 1558 2342.1 m. (d) SEM-BS image of a clay clump (white arrows) between detrital grains. White 1559 minerals are pyrite; sample 9P, well 2, 2366.25 m. (e) SEM-SE image of authigenic pore lining 1560 kaolinite, sample A, well 16, 875.55 m. (f) SEM-SE image of pore bridging fibrous illite, 1561 developing on detrital clay, sample 1, well 1, 2006 m.

**Fig 10:** Carbonate minerals. Thin section photomicrograph showing euhedral dolomite cement (Dc) surrounding a detrital dolomite (Dd) core. Note pyrite (Py) inclusions in the dolomite cement, sample 1AC, well 15, 867 m. (b) SEM-EDS (left) and SEM-CL (blue channel, right) of detrital dolomite (Dd), surrounded by dolomite cement (Dc) and Fe-rich dolomite cement (Fe-Dc). Small dissolution pits (yellow arrows) are present in the detrital dolomite,

1567 sample 16I, well 2, 2487 m. (c) SEM-CL image showing detrital dolomite and cement. Outer rim 1568 is composed of non-luminescent Fe-dolomite. Fe-dolomite cement is replacing earlier dolomite 1569 cement with bright blue luminescence (yellow arrows), sample 3AJ, well 4, 2653 m. (d) Large 1570 dissolution vuggs in dolomite (in both detrital well and cement), sample 1AE, well 15, 864.9 m. (e) Poikilotopic calcite cement in SEM-EDS image. Sample 3AJ, well 4, 2653 m.(f) SEM-EDS 1571 1572 image showing calcite filling pores left by dissolution of detrital dolomite, sample 3E, well 2, 1573 2281 m. (g) SEM-EDS (left) and SEM-CL (right) showing two generations of calcite. The first 1574 calcite cement generation (Ca<sub>1</sub>) contains euhedral pyrite inclusions and has bright 1575 luminescence. The second calcite cement generation (Ca<sub>2</sub>) crystallized around Ca<sub>1</sub>, has darker, more muted blue luminescence pattern than Ca<sub>1</sub>. (h) Moldic porosity in dolomite cement, 1576 sample 170803, well 13, 1960.5 m. (i) Phosphate replacing fossils, sample 2AE, well 4, 2621 m. 1577

1578 Fig. 11: Organic matter and minor mineral phases in the Montney Formation. (a) BS-SEM 1579 image of pyrite framboids and pyrite crystals (white) within the siltstone matrix. Note abundant organic matter (OM) plugging pores. Sample, 3A, well 2, 2285 m. (b) SE-SEM image of a pyrite 1580 1581 framboids coated in detrital clay. Clay coats suggest pyrite framboids were transported from the original site of precipitation, sample 6, well 1, 1986 m. (c) QEMSCAN image of bedding -parallel 1582 1583 anhydrite (pink color), sample 3B, well 9, 3340 m. (d) QEMSCAN image showing phosphatic 1584 nodules (salmon color), sample 170940, well 10, 1794.5 m. (e) EDS- SEM image showing (1) 1585 phosphate incorporated into dolomite (white arrow), and (2) phosphate precipitating at the 1586 boundary of a dolomite grain (white arrow), together with pyrite (white crystals), sample 3E, well 1587 2, 2281 m. (f) BSE-SEM image showing organic matter (red arrows) filling secondary porosity in dolomite. Blue arrows point to pores which show darker on BSE images. Sample 1AE, core 15, 1588 864.9 m. 1589

**Fig. 12:** Macroporosity values obtained from QEMSCAN analysis (pores > 4.8) and matrix porosity (pores> 0.31 Å). Matrix porosity is consistently higher than porosity measured through

1592 QEMSCAN analysis indicating that a large fraction of the pores in the samples consists of1593 micropores, smaller than 4.8 μm.

**Fig. 13:** Paragenetic sequence for the Montney Formation. Burial diagram adopted from well C-70-B/93-P-9 of Ducros et al. (2017). (a) Detrital component slightly dissolved on seabed include dolomite, feldspars and chert (b) Process continues in the deep section of the basin when temperatures are currently 100°C or higher (c) Albitization (d) Process developed only in the shallow section of the basin.

**Fig. 14:** Pressure solution in Montney samples. (a) SEM-EDS image (left) and SEM-CL image (right) of pressure solutions (white arrow) between a detrital quartz grain (Qd) and quartz cement (Qc). Sample 5N, well 9, 3376m. (b) SEM-EDS image (left) showing quartz grains with morphology that resembles pressure solution (white arrow). SEM-CL image (right) confirms pressure solution between two detrital quartz grains (Qd). Sample 2AQ, well 9, 3289 m.

Fig. 15: Porosity/ IGV depth plot for silt-rich sediment (black line), clean, well-sorted
sandstone (blue line), and shale (red line). The rate of mechanical compaction is the main
control over porosity reduction with depth, but cement halts compaction. If cement is present,
the IGV value can indicates the depth of cementation.

Green arrows show the cementation depths of three samples from the Montney siltstone. (a) sample depth is 2653 m, but an IGV of 52% indicates cementation occurred at ~150 m depth (sample 3AJ, well 4). (b) sample depth is 3278 m, but an IGV of 40% indicates cementation occurred at 500 m depth (sample 1C, well 9). (c) sample depth is 2739 m, but an IGV of 27.6% indicates cementation occurred at 1000 m depth (Sample 5V, well 4). Samples with IGV > 60% (initial porosity) could not be placed on the compaction graph. Such high IGV value suggests that a portion of the detrital grains was dissolved or that the initial porosity is larger than 60%.

1615 Fig. 16: calculated (close symbols) and measured (open symbols) detrital quartz grain size versus different cements for the three lithofacies groups in the Montney formation. Cement 1616 1617 volumes were calculated from QEMSCAN analysis results based on the average cement 1618 content of each mineral per facies, obtained from point count analysis (Table 4). Note that the 1619 calculated volumes of quartz cement fit reasonably well within the error of the measured data 1620 from point count analysis. No clear distinction between samples from different groups exist in 1621 any of the graphs although it is possible that the large error associated with the measured 1622 detrital grain size (not depicted in the figure) may be masking such correlations. (a) Quartz 1623 cement volume versus detrital quartz grain size. Quartz cement volume vary greatly for any given grain size, suggesting that detrital grain size is not the main factor controlling the volume 1624 of quartz cement. (b) Quartz cement versus clay content. Samples from lithofacies group one 1625 1626 have the lowest amount of clay and high quartz cement volume, and samples from lithofacies 1627 group three have higher clay concentration but similarly high guartz cement volume. 1628 demonstrating that higher clay concentration in the matrix does not equate more extensive clay 1629 coats on detrital grains. Lithofacies in group one have the highest bioturbation index and thus 1630 the highest probability to have clay coats generated through bioturbation. Respectively, samples 1631 from this group have the lowest volume of quartz cement. Here too, it is possible that the large 1632 error associated with the measured detrital grain size may be masking a correlation between the 1633 volume of quartz cement and clay content. (c) Detrital guartz grain size and total cements 1634 volume. Total cements volume includes quartz, feldspar, dolomite, calcite, anhydrite, pyrite, 1635 halite and phosphate. No correlation exists between detrital quartz grain size and dolomite 1636 cement or total cement volume. (d) Detrital guartz grain size and calcite cements. No correlation 1637 exists between detrital quartz grain size and calcite cement. Most samples from group one 1638 which have the largest grain size, have the lowest amount of calcite cement.

**Fig. 17:** Mineralogical composition of the Montney Formation (black diamonds, gray envelope) compared to various shale formations (after Chermak and Schreiber, 2014). The Montney Formation is most similar to the Barnett (blue rectangles, till envelope), but contains similar or lower clay concentrations, and for the most part less carbonate minerals than other shales.

1644 **9. Tables:**

amount of K-feldspar albitization and silica liberated during smectite illitization.

All calculations done for 100 gr of rock.

<sup>a</sup>concentration from QEMSCAN analysis.

<sup>b</sup>concentration of detrital smectite assuming original composition of illite (80)/smectite (20) and final composition of illite (95)/ smectite (5).

<sup>c</sup>according to molar ratios from Eq.1.

<sup>d</sup>according to point count analysis albitized Kspar is 12.6% of total Na-feldspar.

<sup>e</sup>K+ released by Na-feldspar albitization is equal to Na<sup>+</sup> consumed by the albitization reaction.

<sup>f</sup> K+ released by Na-feldspar albitization and not consumed by conversion of smectite to illite.

<sup>g</sup> Silica released by smectite to illitization.

Appendix 3: Correlation between average quartz mineral size measured through QEMSCAN analysis and average detrital quartz grain size measured from SEM-images.

Appendix 4: Rock composition and **Mineral size from** QEMSCAN analysis for seven wells in the Montney Formation. Dark gray area shows results between P<sub>5</sub> and P9<sub>5</sub>., light gray areas are the upper and lower 5<sup>th</sup> percentiles (minimum and maximum), and the dashed line is the median value.

For graphs depicting minerals content, point count averages (full circles), and XRD ranges and average compositions (diamonds, error bars) are superimposed on QEMSCAN results and show good agreement. (a) Quartz content (c) K-feldspar (e) Na-feldspar (g) mica (i) Calcite (k) dolomite (m) total clay content; no XRD results are presented, since XRD analysis cannot distinguish between muscovite and illite. (n) kaolinite content (o) total organic carbon content.

Mineral size was obtained from QEMSCAN analysis. (a) Quartz; Circles are average detrital quartz grain size obtained from SEM-CL analysis (d) K-feldspar (f) Na-feldspar (h) mica (j) Calcite (l) dolomite.

(a) Dissolved detrital components include dolomite, feldspar, chert.

(b) Quartz cment related to pressure solution. It is possible that the two generations of quartz cement are temporaly continous.

(c) Relationship between fibrous illite and HC emplacement is not clear.

(d) Pressure solution was potential active at shallow depth due to microfractures in quartz grains.

(e) Pressure solution is still an active process in the deeply burried section of the basin.

(f) Dissolution related to HC emplacement.

(g) Dissolution in the eastern (shallow) section of the basin related to meteoric water.

(h) In the eastern (shallow) section of the basin illite precipitation postdates kaolinite precipitation.
